CLINICAL KEY™

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey
is specifically designed to serve doctors by providing
three core components:**

**1 Comprehensive
Content**

The most current, evidence-based answers available for every medical and surgical specialty.

**2 Trusted
Answers**

Content supplied by Elsevier, the world's leading provider of health and science information.

**3 Unrivalled Speed
to Answer**

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit **ClinicalKey.com** for more information
and subscription options.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*To my wife, Amy, who gives me love, inspiration,
and unwavering support and to our children,
Michelle, Eric, Nicholas, and Amanda.
They provide us with unlimited pleasure.*

FWS

*To Martha, my loving wife, and to my children,
Alexander and his wife Erika, to Sara, Daniel,
Elizabeth, and to my grandson Matthew who keeps
reminding us of the important things in life.
Thank you.*

PJD

*To my mother, Anne Parkhurst, and my wife,
Donna, and our children, Whit, Kate, and Maggie:
I am very appreciative and grateful for the guidance,
love, and support; gives meaning to all of what I do.
To my patients: the inspiration to work hard and do
better every day.*

 Surgery
 Chair, Department of Cardiac Surgery
 Professor of Cardiac Surgery
 Professor of Pediatrics and Communicable Disease
 University of Michigan
 Ann Arbor, Michigan

William J. Brawn, CBE, FRCS, FRACS

Consultant Cardiac Surgeon
 Birmingham Children's Hospital
 NHS Foundation Trust
 Birmingham, United Kingdom

Christian P. Brizard, MD

Associate Professor
 University of Melbourne Faculty of Medicine,
 Dentistry
 Health Sciences School of Medicine
 Cardiac Surgery Unit
 Royal Children's Hospital
 Melbourne, Victoria, Australia

Julie A. Brothers, MD

Assistant Professor of Pediatrics
Perelman School of Medicine
University of Pennsylvania
Attending Physician, Cardiology
Medical Director, Coronary Anomaly Management
Program
Medical Director, Lipid Heart Clinic
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Lisa M. Brown, MD, MAS

Cardiothoracic Surgery Fellow
Division of Cardiothoracic Surgery
Washington University
St. Louis, Missouri

Ayesha S. Bryant, MD

Assistant Professor of Surgery
Division of Cardiothoracic Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Harold M. Burkhart, MD

Professor of Surgery
Section of Cardiothoracic Surgery
The University of Oklahoma Health Sciences School of
Medicine
Director of Pediatric Cardiovascular Surgery
Medical Director of Pediatric Cardiovascular Surgical
Services
The Children's Hospital
Oklahoma City, Oklahoma

Christopher A. Caldarone, MD, FRCSC

Cardiovascular Surgery
The Hospital for Sick Children
Toronto, Ontario, Canada

Jeremy W. Cannon, MD, SM, FACS

Lieutenant Colonel, U.S. Air Force
Chief, Trauma and Critical Care
San Antonio Military Medical Center
San Antonio, Texas
Associate Professor of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Justine M. Carr, MD

Chief Medical Officer
Steward Health Care System
Senior Director, Department of Clinical Resource
Management
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Serenella Castelvechio, MD

Department of Cardiac Surgery
IRCCS Policlinico San Donato
Milan, Italy

Javier G. Castillo, MD

Department of Cardiovascular Surgery
The Mount Sinai Medical Center
New York, New York

Frank Cecchin, MD

Professor of Pediatrics
Pediatric Cardiology
New York University
New York, New York

Robert J. Cerfolio, MD

Chief of Thoracic Surgery
Professor of Cardiothoracic Surgery
University of Alabama at Birmingham
Birmingham, Alabama

A. Alfred Chahine, MD

Associate Professor of Surgery and Pediatrics
George Washington University School of Medicine
Attending Surgeon
Children's National Medical Center
Chief of Pediatric Surgery
MedStar Georgetown University Hospital
Washington, DC

Elliot L. Chaikof, MD, PhD

Johnson and Johnson Professor of Surgery
Chairman, Roberta and Stephen R. Weiner
Department of Surgery
Harvard Medical School
Surgeon-in-Chief
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Vincent Chan, MD, MPH

Assistant Professor
Division of Cardiac Surgery
University of Ottawa Heart Institute
Ottawa, Ontario, Canada

Sunit-Preet Chaudhry, MD

Cardiovascular Institute
Warren Alpert Medical School of Brown University
Providence, Rhode Island

Frederick Y. Chen, MD, PhD

Associate Professor of Cardiac Surgery
Harvard Medical School
Department of Surgery
Division of Cardiac Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Stuart H. Chen, MD

Clinical Fellow in Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Aaron M. Cheng, MD

Assistant Professor
Division of Cardiothoracic Surgery
University of Washington
Seattle, Washington

Victor Chien, MD

Research Fellow in Surgery
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Alvin J. Chin, MD

Professor of Pediatrics, Emeritus
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Cynthia S. Chin, MD

Director of the Women's Cancer Program Services
Thoracic Surgery
White Plains Hospital
White Plains, New York

Peter Chiu, MD

Resident, Department of Cardiothoracic Surgery
Stanford University School of Medicine
Stanford, California

Joseph C. Cleveland, Jr., MD

Professor of Cardiothoracic Surgery
Surgical Director, Cardiac Transplantation and MCS
University of Colorado Anschutz Medical Center
Aurora, Colorado

Lawrence H. Cohn, MD

Hubbard Professor of Cardiac Surgery
Harvard Medical School
Department of Surgery
Division of Cardiac Surgery
Brigham and Women's Hospital
Boston, Massachusetts

William E. Cohn, MD

Professor of Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Director, Center for Technology and Innovation
Director, Cullen Cardiovascular Research Laboratory
Texas Heart Institute
Houston, Texas

Yolonda L. Colson, MD, PhD

Professor
Department of Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Wilson S. Colucci, MD

Thomas J. Ryan Professor of Medicine
Professor of Physiology
Boston University School of Medicine
Chief, Section of Cardiovascular Medicine
Co-Director, Cardiovascular Center
Boston Medical Center
Boston, Massachusetts

Andrew C. Cook, PhD

Senior Lecturer
Cardiac Unit
UCL Institute of Cardiovascular Science
Great Ormond Street Hospital
NHS Foundation Trust
London, United Kingdom

Joseph S. Coselli, MD

Professor and Chief
Division of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Chief, Section of Adult Cardiac Surgery
The Texas Heart Institute
Houston, Texas

Todd C. Crawford, MD

Division of Thoracic Surgery
The Johns Hopkins Medical Institutions
Baltimore, Maryland

Melissa Culligan, BSN, RN

Department of Thoracic Surgery
University of Pennsylvania Health System—Presbyterian
Philadelphia, Pennsylvania

François Dagenais, MD, FRCSC

Institut Universitaire de Cardiologie et de Pneumologie
de Québec
Québec City, Québec, Canada

Ralph J. Damiano, Jr., MD

Evarts A. Graham Professor of Surgery
Chief, Division of Cardiothoracic Surgery
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, Missouri

Thomas A. D'Amico, MD

Gary Hock Endowed Professor and Vice Chair of
Surgery
Duke University School of Medicine
Chief, Section of General Thoracic Surgery
Program Director, Thoracic Surgery
Duke University Medical Center
Durham, North Carolina

Philippe G. Dartevelle, MD

Head, Service de Chirurgie Thoracique, Vasculaire et
Transplantation Cardiopulmonaire
Hôpital Marie Lannelongue
Le Plessis Robinson, France

Tirone E. David, MD

Professor of Surgery
University of Toronto
Attending Surgeon
Peter Munk Cardiac Centre
Toronto General Hospital
Toronto, Ontario, Canada

Jonathan D'Cunha, MD, PhD

Associate Professor of Surgery
Vice Chairman, Academic Affairs and Education
Surgical Director, Lung Transplantation
Associate Program Director, Thoracic Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

Kim I. de la Cruz, MD

Assistant Professor of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Clinical Staff
The Texas Heart Institute
Houston, Texas

Joseph A. Dearani, MD

Professor of Surgery
Chair, Cardiac Surgery
Division of Cardiovascular Surgery
Mayo Clinic
Rochester, Minnesota

Daniel T. DeArmond, MD

Cardiothoracic Surgery
University of Texas Health Science Center
San Antonio, Texas

Pedro J. del Nido, MD

William E. Ladd Professor of Surgery
Harvard Medical School
Chairman, Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Tom R. DeMeester, MD

Professor and Chairman, Emeritus
Department of Surgery
University of Southern California
Los Angeles, California

Philippe Demers, MD, MSC, FRCSC

Associate Professor of Surgery
Cardiac Surgery
University of Montreal
Cardiovascular Surgeon
Montreal Heart Institute
Montreal, Quebec, Canada

Todd L. Demmy, MD

Chairman, Department of Thoracic Surgery
Roswell Park Cancer Institute
Buffalo, New York

Elisabeth U. Dexter, MD

Assistant Professor of Oncology
Department of Thoracic Surgery
Roswell Park Cancer Institute
Assistant Professor of Surgery
SUNY University at Buffalo
Buffalo, New York

Rajeev Dhupar, MD

Assistant Professor of Surgery
Department of Cardiothoracic Surgery
Division of Thoracic and Foregut Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

James A. DiNardo, MD

Professor of Anesthesia
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

Thomas P. Doyle, MD

Associate Professor of Pediatrics
Division of Cardiology
Vanderbilt University School of Medicine
Nashville, Tennessee

Afshin Ehsan, MD

Assistant Professor of Surgery
Brown Alpert Medical School
Rhode Island Hospital
Providence, Rhode Island

Gebrine El Khoury, MD, PhD

Professor
Department of Cardiovascular and Thoracic Surgery
Cliniques Universitaires Saint-Luc
Brussels, Belgium

Ethan R. Ellis, MD

Harvard-Thorndike Electrophysiology Institute
Cardiovascular Division
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Nassrene Y. Elmadhun, MD

Research Fellow
Cardiovascular Research Center
Warren Alpert Medical School
Brown University
Providence, Rhode Island
Surgical Resident
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Sitaram M. Emani, MD

Assistant Professor in Surgery
 Harvard Medical School
 Assistant in Cardiac Surgery
 Surgical Director, Adult Congenital Heart Program
 Director, Complex Biventricular Repair Program
 Surgical Director, Division of Cardiovascular Critical Care
 Boston Children's Hospital
 Boston, Massachusetts

Jeremy J. Erasmus, MD

Professor
 Department of Diagnostic Imaging
 The University of Texas MD Anderson Cancer Center
 Houston, Texas

Dario O. Fauza, MD

Associate Professor of Surgery
 Harvard Medical School
 Associate in Surgery
 Boston Children's Hospital
 Boston, Massachusetts

Adam S. Fein, MD

Cardiac Services
 Beth Israel Deaconess Medical Center
 Boston, Massachusetts

Amy G. Fiedler, MD

Clinical Fellow in Surgery
 Department of Surgery
 Division of Cardiac Surgery
 Brigham and Women's Hospital
 Boston, Massachusetts

Murilo Foppa, MD, DSc

Department of Medicine
 Cardiovascular Division
 Harvard-Thorndike Laboratory
 Harvard Medical School
 Beth Israel Deaconess Medical Center
 Boston, Massachusetts;
 Division of Cardiology
 Hospital de Clinicas de Porto Alegre
 Federal University of Rio Grande do Sul
 Brazil

Rosario V. Freeman, MD, MS

Medical Director, Echocardiography
 Program Director, Cardiology Fellowship Programs
 University of Washington
 Seattle, Washington

Joseph Friedberg, MD, FACS

Chief of Thoracic Surgery
 University of Pennsylvania Health System–Presbyterian
 Philadelphia, Pennsylvania

Michael Friscia, MD

Associate, Thoracic and Cardiac Surgery
 Geisinger Health System
 Danville, Pennsylvania

Francis Fynn-Thompson, MD

Assistant Professor of Surgery
 Surgical Director, Heart and Lung Transplantation
 Surgical Director, Mechanical Circulatory Support Program
 Program Director, Congenital Cardiac Surgery
 Residency/Fellowship
 Department of Cardiac Surgery
 Boston Children's Hospital
 Harvard Medical School
 Boston, Massachusetts

J. William Gaynor, MD

Professor of Surgery
 Perelman School of Medicine
 University of Pennsylvania
 Attending Surgeon
 Director, Fetal Neuroprotection and Neuroplasticity Program
 Daniel M. Tabas Endowed Chair, Pediatric Cardiothoracic Surgery
 The Children's Hospital of Philadelphia
 Philadelphia, Pennsylvania

Liang Ge, PhD

Assistant Professor of Surgery
 Department of Surgery
 University of California, San Francisco School of Medicine
 Department of Surgery
 San Francisco VA Medical Center
 San Francisco, California

Tal Geva, MD

Professor of Pediatrics
 Harvard Medical School
 Chief, Division of Noninvasive Cardiac Imaging
 Senior Associate, Department of Cardiology
 Boston Children's Hospital
 Boston, Massachusetts

Neil M. Gheewala, MD

Cardiovascular Institute
 Warren Alpert Medical School of Brown University
 Providence, Rhode Island

A. Marc Gillinov, MD

The Judith Dion Pyle Chair in Heart Valve Research
 Department of Thoracic and Cardiovascular Surgery
 Cleveland Clinic
 Cleveland, Ohio

Donald D. Glower, MD

Professor of Surgery
Department of Surgery
Division of Cardiovascular and Thoracic Surgery
Duke University School of Medicine
Durham, North Carolina

Andrew B. Goldstone, MD

Postdoctoral Research Fellow
Department of Cardiothoracic Surgery
Stanford University School of Medicine
Stanford, California

Shawn S. Groth, MD, MS

Assistant Professor of Surgery
Division of General Thoracic Surgery
Baylor College of Medicine
Houston, Texas

Frederick L. Grover, MD

Professor of Cardiothoracic Surgery
University of Colorado Anschutz Medical Center
Aurora, Colorado

Julius Guccione, PhD

Professor of Surgery
Department of Surgery
University of California, San Francisco School of
Medicine
Associate Professor of Surgery
San Francisco VA Medical Center
San Francisco, California

Richard Ha, MD

Clinical Assistant Professor
Surgical Director, Mechanical Circulatory Support
Program
Department of Cardiothoracic Surgery
Stanford University School of Medicine
Stanford, California

John W. Hammon, MD

Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

Jennifer M. Hanna, MD

Resident, General Surgery
Duke University School of Medicine
Durham, North Carolina

David G. Harrison, MD

Betty and Jack Bailey Professor of Medicine and
Pharmacology
Director, Division of Clinical Pharmacology
Director, Center for Vascular Biology
Vanderbilt University Medical Center
Nashville, Tennessee

Thomas H. Hauser, MD, MMSc, MPH

Department of Medicine
Cardiovascular Division
Harvard-Thorndike Laboratory
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Matthew C. Henn, MD

Resident, Division of Cardiothoracic Surgery
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, Missouri

Jennifer C. Hirsch-Romano, MD

Assistant Professor of Cardiac Surgery
University of Michigan
Ann Arbor, Michigan

Chuong D. Hoang, MD

Assistant Professor
Department of Cardiothoracic Surgery
Division of Thoracic Surgery
Stanford University School of Medicine
Stanford, California

Wayne L. Hofstetter, MD

Professor of Surgery
Director of Esophageal Surgery
Department of Thoracic and Cardiovascular Surgery
The University of Texas MD Anderson Cancer Center
Houston, Texas

Osami Honjo, MD, PhD

Cardiovascular Surgery
The Hospital for Sick Children
Toronto, Ontario, Canada

Tam T. Huynh, MD

Professor
Department of Thoracic and Cardiovascular Surgery
The University of Texas MD Anderson Cancer Center
Houston, Texas

Carlos E. Bravo Iñiguez, MD

Postdoctoral Fellow
Division of Thoracic Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Sebastian Iturra, MD

Structural Heart and Valve Center
Division of Cardiothoracic Surgery
Joseph B. Whitehead Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Jeffrey P. Jacobs, MD, FACS, FACC, FCCP

Professor of Surgery
 Division of Cardiac Surgery
 Department of Surgery
 Johns Hopkins University
 Baltimore, Maryland;
 Chief, Division of Cardiovascular Surgery
 Director, Andrews/Daicoff Cardiovascular Program
 Surgical Director of Heart Transplantation and
 Extracorporeal Life Support Programs
 Johns Hopkins All Children's Heart Institute
 All Children's Hospital and Florida Hospital for
 Children
 Saint Petersburg, Tampa, and Orlando, Florida

Marshall L. Jacobs, MD

Division of Cardiac Surgery
 Department of Surgery
 Johns Hopkins University
 Baltimore, Maryland

Michael T. Jaklitsch, MD

Associate Professor
 Surgeon, Division of Thoracic Surgery
 Brigham & Women's Hospital
 Harvard Medical School
 Boston, Massachusetts

Stuart W. Jamieson, MB, FRCS

Distinguished Professor of Surgery
 Endowed Chair, Division of Cardiothoracic Surgery
 University of California, San Diego
 San Diego, California

Doraid Jarrar, MD

Thoracic Surgeon
 Einstein Healthcare
 East Norriton, Pennsylvania

Craig M. Jarrett, MD

Department of Thoracic and Cardiovascular Surgery
 Cleveland Clinic
 Cleveland, Ohio

David R. Jones, MD

Professor and Chief of Thoracic Surgery
 Memorial Sloan-Kettering Cancer Center
 New York, New York

Mark E. Josephson, MD

Harvard-Thorndike Electrophysiology Institute,
 Cardiovascular Division
 Harvard Medical School
 Beth Israel Deaconess Medical Center
 Boston, Massachusetts

Lilian P. Joventino, MD

Wentworth Health Partners Cardiovascular Group
 Dover, New Hampshire

Amy L. Juraszek, MD

Associate Professor
 Departments of Pediatrics and Pathology
 University of Texas Southwestern Medical Center
 Dallas, Texas

Stefan S. Kachala, MD

Department of Thoracic and Cardiovascular Surgery
 Cleveland Clinic
 Cleveland, Ohio

Larry R. Kaiser, MD

Dean and Professor of Surgery
 Temple University School of Medicine
 President and CEO
 Temple University Health System
 Sr. Executive Vice President for the Health Sciences
 Temple University
 Philadelphia, Pennsylvania

Kirk R. Kanter, MD

Professor of Surgery
 Pediatric Cardiac Surgery
 Emory University School of Medicine
 Atlanta, Georgia

John M. Karamichalis, MD

Clinical Instructor in Surgery
 Department of Surgery
 Division of Pediatric Cardiothoracic Surgery
 University of California, San Francisco
 San Francisco, California

Aditya K. Kaza, MD

Assistant Professor of Surgery
 Harvard Medical School
 Associate in Cardiac Surgery
 Department of Cardiac Surgery
 Boston Children's Hospital
 Boston, Massachusetts

Clinton D. Kemp, MD

Division of Thoracic Surgery
 The Johns Hopkins Medical Institutions
 Baltimore, Maryland

Kemp H. Kernstine, Sr., MD, PhD

Professor and Chief, Division of Thoracic Surgery
 Department of Cardiovascular & Thoracic Surgery
 University of Texas Southwestern Medical Center
 Dallas, Texas

Suresh Keshavamurthy, MD

Cleveland Clinic
 Cleveland, Ohio

Shaf Keshavjee, MD, MSc, FRCS, FACS

Surgeon-in-Chief, University Health Network
 James Wallace McCutcheon Chair in Surgery
 Professor, Division of Thoracic Surgery
 University of Toronto
 Toronto, Ontario, Canada

Deborah J. Kozik, DO

Assistant Professor of Surgery
Department of Cardiovascular and Thoracic Surgery
University of Louisville
Cardiothoracic Surgery
Kosair Children's Hospital
Louisville, Kentucky

Roger J. Laham, MD

Associate Professor of Medicine
Harvard Medical School
Research Investigator
CardioVascular Institute
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Michael J. Landzberg, MD

Director, Boston Adult Congenital Heart (BACH) and
Pulmonary Hypertension Program
Department of Cardiology
Brigham and Women's Hospital and Boston Children's
Hospital
Boston, Massachusetts

Christopher P. Lawrance, MD

Resident, Division of Cardiothoracic Surgery
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, Missouri

Lawrence S. Lee, MD

Clinical Fellow in Surgery
Harvard Medical School
Department of Surgery
Division of Cardiac Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Scott A. LeMaire, MD

Professor and Vice Chair for Research
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Professional Staff, Department of Cardiovascular
Surgery
The Texas Heart Institute
Houston, Texas

Sidney Levitsky, MD

David W. and David Cheever Professor of Surgery
Harvard Medical School
Director, Cardiothoracic Surgery Care Group
Senior Vice Chairman, Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Jerrold H. Levy, MD, FAHA, FCCM

Professor of Anesthesiology
Associate Professor of Surgery
Departments of Anesthesiology, Surgery, and Critical
Care
Co-Director, Cardiothoracic ICU
Duke University School of Medicine
Duke University Medical Center
Durham, North Carolina

Philip A. Linden, MD

Associate Professor of Surgery
Case Western Reserve School of Medicine
Chief, Division of Thoracic and Esophageal Surgery
University Hospitals Case Medical Center
Cleveland, Ohio

Michael J. Liptay, MD

The Mary and John Bent Professor and Chairperson
Department of Cardiovascular and Thoracic Surgery
Rush University Medical Center
Chicago, Illinois

Virginia R. Litle, MD, FACS

Associate Professor of Surgery
Department of Surgery
Division of Thoracic Surgery
Boston University School of Medicine
Boston, Massachusetts

Mauro Lo Rito, MD

Cardiovascular Surgery
The Hospital for Sick Children
Toronto, Ontario, Canada

James D. Luketich, MD

Henry T. Bahnson Professor and Chairman
Department of Cardiothoracic Surgery
Chief, Division of Thoracic and Foregut Surgery
University of Pittsburgh School of Medicine
Director, Thoracic Surgical Oncology
Co-Director, Lung Cancer Center
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Bruce W. Lytle, MD

Chairman, Strategic Development and Planning
for Cardiovascular Medicine and Surgery
The Heart Hospital Baylor Plano
Plano, Texas

Michael Madani, MD

Professor of Surgery
Chief, Division of Cardiothoracic Surgery
University of California, San Diego
San Diego, California

Feroze Mahmood, MD

Associate Professor of Anaesthesiology
Harvard Medical School
Director, Vascular Anesthesia/Perioperative
Echocardiography
Beth Israel Deaconess Medical Center
Harvard Medical Faculty Physicians at Beth Israel
Deaconess Medical Center
Boston, Massachusetts

Hari R. Mallidi, MD

Associate Professor of Surgery
Chief, Division of Transplant & Assist Devices
Lester and Sue Smith Endowed Chair in Surgery
Baylor College of Medicine
Houston, Texas

Abeel A. Mangi, MD

Associate Professor of Surgery, Section of Cardiac
Surgery
Surgical Director, Center for Advanced Heart Failure,
Mechanical Circulatory Support and Heart
Transplantation
Surgical Director, Trans-Catheter Therapies
Yale University
New Haven, Connecticut

Warren J. Manning, MD

Departments of Medicine and Radiology
Cardiovascular Division
Harvard-Thorndike Laboratory
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Edith M. Marom, MD

Professor
Department of Diagnostic Imaging
The University of Texas MD Anderson Cancer Center
Houston, Texas

Audrey C. Marshall, MD

Chief, Invasive Cardiology
Boston Children's Hospital
Boston, Massachusetts

Mauricio Perez Martinez, MD

Division of Thoracic Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Christopher E. Mascio, MD

Assistant Professor of Clinical Medicine
Perelman School of Medicine
University of Pennsylvania
Pediatric Cardiothoracic Surgeon
Division of Cardiothoracic Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David P. Mason, MD

Chief, Thoracic Surgery and Lung Transplantation
Department of Thoracic Surgery
Baylor University Medical Center
Dallas, Texas

Douglas J. Mathisen, MD

Chief of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Kenneth L. Mattox, MD, FACS

Professor of Surgery
Division of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Robina Matyal, MD

Associate Professor of Anaesthesiology
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

James D. McCully, PhD

Associate Professor of Surgery
Harvard Medical School
Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Robert J. McKenna, Jr., MD

Director, Thoracic Surgery
Surgery
Cedars-Sinai Medical Center
Los Angeles, California

Ciaran McNamee, MD

Instructor in Surgery
Harvard Medical School
Associate Surgeon
Brigham and Women's Hospital
Boston, Massachusetts

Jeffrey D. McNeil, MD

Colonel, U.S. Air Force
Chief, Cardiothoracic Surgery Service
San Antonio Military Medical Center
San Antonio, Texas
Clinical Assistant Professor, Cardiothoracic Surgery
University of Texas Health Science Center, San
Antonio
San Antonio, Texas

Lorenzo Menicanti, MD

Chief of Cardiac Surgery
IRCCS Policlinico San Donato
Milan, Italy

Carlos A. Mestres, MD, PhD, FETCS

Senior Consultant
Department of Cardiovascular Surgery
Hospital Clinico
University of Barcelona
Barcelona, Spain;
Cardiothoracic and Vascular Surgery
Heart and Vascular Institute
Cleveland Clinic Abu Dhabi
Abu Dhabi, United Arab Emirates

Bret A. Mettler, MD

Assistant Professor
Division of Pediatric Cardiac Surgery
Vanderbilt University School of Medicine
Department of Cardiac Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Bryan Fitch Meyers, MD, MPH

Patrick and Joy Williamson Professor of Surgery
Chief, Thoracic Surgery
Washington University School of Medicine
St. Louis, Missouri

Stephanie Mick, MD

Cardiovascular Surgeon
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Tomislav Mihaljevic, MD

Chief of Staff and Chairman of the Heart and Vascular
Institute
Cleveland Clinic Abu Dhabi
Abu Dhabi, United Arab Emirates;
Attending Surgeon
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Professor of Surgery
Cleveland Clinic Lerner College of Medicine at Case
Western University
Cleveland, Ohio

Carmelo A. Milano, MD

Professor of Surgery
Cardiovascular and Thoracic Surgery
Duke University
Durham, North Carolina

D. Craig Miller, MD

Thelma and Henry Doelger Professor of
Cardiovascular Surgery
Department of Cardiovascular Surgery
Stanford University School of Medicine
Department of Cardiothoracic Surgery
Stanford University Medical Center
Stanford, California

Daniel L. Miller, MD, FACS

Clinical Professor of Surgery
Georgia Regents University
Chief, General Thoracic Surgery
WellStar Health System
Mayo Clinic Care Network
Marietta, Georgia

Meagan M. Miller, RN, BSN

Vanderbilt University Medical Center
Nashville, Tennessee

John D. Mitchell, MD

Courtenay C. and Lucy Patten Davis Endowed Chair
in Thoracic Surgery
Professor and Chief, Section of General Thoracic
Surgery
Division of Cardiothoracic Surgery
University of Colorado School of Medicine
Aurora, Colorado

Mario Montealegre-Gallegos, MD

Department of Anaesthesia
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Neal G. Moores, MD

Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Charles E. Murphy, MD

Assistant Professor of Surgery
Division of Cardiovascular and Thoracic Surgery
Duke University School of Medicine
Duke University Medical Center
Durham, North Carolina

Raghav A. Murthy, MD

Department of Cardiovascular & Thoracic Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Sudish C. Murthy, MD, PhD

Section Head, General Thoracic Surgery
Surgical Director, Center for Major Airway Disease
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Sacha Mussot, MD

Hôpital Marie Lannelongue
Service de Chirurgie Thoracique, Vasculaire et
Transplantation Cardiopulmonaire
Le Plessis Robinson, France

Yoshifumi Naka, MD, PhD

Professor of Surgery
Columbia University College of Physicians and Surgeons
Attending Surgeon
New York–Presbyterian Hospital
New York, New York

Meena Nathan, MD, FRCS

Instructor in Surgery
Harvard Medical School
Staff Cardiac Surgeon
Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Kurt D. Newman, MD

President and Chief Executive Officer
Children's National Medical Center
Washington, DC

Chukwumere Nwogu, MD

Associate Professor
Department of Thoracic Surgery
Roswell Park Cancer Institute
Buffalo, New York

Kirsten C. Odegard, MD

Associate Professor
Department of Anesthesiology, Perioperative and Pain Medicine
Boston Children's Hospital
Boston, Massachusetts

Daniel S. Oh, MD

Assistant Professor of Surgery
Division of Thoracic Surgery
University of Southern California
Los Angeles, California

Richard G. Ohye, MD

Professor of Cardiac Surgery
University of Michigan
Ann Arbor, Michigan

Mark W. Onaitis, MD

Associate Professor of Surgery
Department of Surgery
Division of Cardiovascular and Thoracic Surgery
Duke University School of Medicine
Duke University Medical Center
Durham, North Carolina

Aleksandra Ostojic, MSc

Division of Cardiac Surgery
University of Ottawa Heart Institute
Department of Cellular and Molecular Medicine
University of Ottawa
Ottawa, Ontario, Canada

Harald C. Ott, MD

Division of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Maral Ouzounian, MD, PhD

Assistant Professor of Surgery
University of Toronto
Cardiovascular Surgeon
Division of Cardiovascular Surgery
University Health Network
Toronto General Hospital
Toronto, Ontario, Canada

Khurram Owais, MD

Department of Anaesthesia
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Department of Cardio Thoracic and Vascular Sciences
University Hospital
Padova, Italy

Konstantinos Papadakis, MD

Instructor in Surgery
Harvard Medical School
Department of Surgery
Boston Children's Hospital
Boston, Massachusetts

G. A. Patterson, MD

Evarts A. Graham Professor of Surgery
Chief, Division of Cardiothoracic Surgery
Washington University
St. Louis, Missouri

Edward F. Patz, Jr., MD

Professor
Department of Radiology
Duke University
Durham, North Carolina

Subroto Paul, MD

Associate Professor
Department of Cardiothoracic Surgery
Weill Cornell Medical College
New York, New York

Arjun Pennathur, MD

Sampson Family Endowed Chair in Thoracic Surgical Oncology
Associate Professor of Cardiothoracic Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Yaron Perry, MD

Clinical Associate Professor of Surgery
Case Western Reserve University School of Medicine
Director, Minimally Invasive Esophageal Surgery
University Hospitals Case Medical Center
Cleveland, Ohio

Robert N. Piana, MD

Professor of Medicine
Division of Cardiovascular Medicine
Director, Adult Congenital Interventional Program
Vanderbilt University Medical Center
Nashville, Tennessee

Frank A. Pigula, MD

Associate Professor of Surgery
Harvard Medical School
Senior Associate in Cardiac Surgery
Clinical Director, Cardiac Surgery Program
Director, Neonatal Cardiac Surgery Program
Boston Children's Hospital
Boston, Massachusetts

Duane S. Pinto, MD, MPH

Associate Professor of Medicine
Harvard Medical School
Associate Director, Cardiac Catheterization Laboratory
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Jose L. Pomar, MD, PhD, FETCS

Senior Consultant and Professor of Surgery
Department of Cardiovascular Surgery
Hospital Clinico
University of Barcelona
Barcelona, Spain

Ourania Preventza, MD

Assistant Professor of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Clinical Staff
The Texas Heart Institute
Houston, Texas

Bradley Pua, MD

Assistant Professor of Radiology
Weill Cornell Medical College
Program Director, Interventional Radiology Fellowship
Director, Lung Cancer Screening Program
New York Presbyterian Hospital/Weill Cornell Medical Center
New York, New York

Varun Puri, MD

Assistant Professor of Surgery
Division of Cardiothoracic Surgery
Washington University
St. Louis, Missouri

Luis Quinonez, MD

Instructor in Surgery
Harvard Medical School
Assistant in Cardiac Surgery
Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Siva Raja, MD, PhD

Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Mark Ratcliffe, MD

Professor of Surgery
Department of Surgery
University of California, San Francisco
Chief Surgical Consultant
Sierra Pacific VA Network
San Francisco, California

Michael J. Reardon, MD

Professor of Cardiothoracic Surgery
Allison Family Distinguished Chair of Cardiovascular Research
Houston Methodist DeBakey Heart & Vascular Center
Houston, Texas

John J. Reilly, Jr., MD

Dean
University of Colorado School of Medicine
Vice Chancellor for Health Affairs
University of Colorado
Aurora, Colorado

Karl G. Reyes, MD

Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Thomas W. Rice, MD

Head, Section of General Thoracic Surgery
Department of Thoracic and Cardiovascular Surgery
Heart and Vascular Institute
Cleveland Clinic
Cleveland, Ohio

Robert C. Robbins, MD

President and Chief Executive Officer
Texas Medical Center
Houston, Texas;
Consulting Professor
Stanford Cardiovascular Institute
Stanford, California

Gaetano Rocco, MD, FRCS(Ed), FECTS

Director, Department of Thoracic Surgery and Oncology
National Cancer Institute, Pascale Foundation
Naples, Italy

Fraser D. Rubens, MD, MSc, FACS, FRCSC

Professor of Surgery
Division of Cardiac Surgery
Residency Program Director
University of Ottawa Heart Institute
Ottawa, Ontario, Canada

Marc Ruel, MD, MPH

Professor and Chair
Division of Cardiac Surgery
University of Ottawa Heart Institute
Ottawa, Ontario, Canada

Valerie W. Rusch, MD

Attending Surgeon, Thoracic Service
Vice Chair for Clinical Research
Miner Family Chair in Intrathoracic Cancers
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Ashraf A. Sabe, MD

Clinical Teaching Fellow, General Surgery
Harvard Medical School
Resident, General Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts;
Research Fellow, Cardiothoracic Surgery
Warren Alpert Medical School of Brown University
Providence, Rhode Island

Sameh M. Said, MD

Senior Associate Consultant
Division of Cardiovascular Surgery
Mayo Clinic
Rochester, Minnesota

Pamela P. Samson, MD, MPH

Resident, Department of Surgery
Washington University and Barnes-Jewish Hospital
St. Louis, Missouri

Stephen P. Sanders, MD

Professor of Pediatrics
Harvard Medical School
Director, Cardiac Registry
Departments of Cardiology, Pathology, Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Eric L. Sarin, MD

Assistant Professor of Surgery
Structural Heart and Valve Center
Division of Cardiothoracic Surgery
Joseph B. Whitehead Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

PREFACE

Since its beginning as a specialty to treat tuberculosis and empyema, thoracic surgery has undergone constant change. Indeed, much has evolved in the fields of adult and pediatric cardiovascular and thoracic surgery even since our last edition. Our new ninth edition contains the latest information on the diagnosis and treatment of disease of the thorax. Especially in such areas as repair of aortic and mitral valvular disease, intervention for congenital heart disease, minimally invasive thoracic and cardiac surgery, surgical treatment of arrhythmias, and endovascular treatment of aortic disease, the field has markedly transformed. As with the previous editions, many of the same authors were asked to update their chapters, but some chapters have been added or eliminated and many others have been completely rewritten. Often new authors were chosen not based on poorly written previous chapters but to provide a novel perspective. We hope that the ninth edition will be received with the same enthusiasm as the last.

Several years ago, we lost one of the former editors of this textbook and a giant in the field of surgery, Dr. David Sabiston. We are fortunate to still have with us another editor, Dr. Frank Spencer. Dr. Spencer is not only one of the true pioneers in our specialty but a great mentor to many in our field. We are all indebted to both Dr. Sabiston and Dr. Spencer for their innumerable contributions to the field of surgery.

Finally, we would like to thank our families for providing immeasurable support not only for this textbook but for our entire careers.

Frank W. Sellke
Pedro J. del Nido
Scott J. Swanson

CONTENTS

VOLUME ■ ONE

SECTION 1 THORACIC SURGERY

PART A EVALUATION AND CARE, 2

- 1 ANATOMY OF THE THORAX, 3
Cynthia S. Chin • Rohit Shahani
- 2 RADIOLOGIC IMAGING OF THORACIC ABNORMALITIES, 26
Jeremy J. Erasmus • Edith M. Marom • Tam T. Huynh • Edward F. Patz, Jr.
- 3 PREOPERATIVE EVALUATION OF PATIENTS UNDERGOING THORACIC SURGERY, 39
John J. Reilly, Jr.
- 4 PERIOPERATIVE CARE OF THE THORACIC SURGICAL PATIENT, 47
Elisabeth U. Dexter

PART B ENDOSCOPY, 71

- 5 ENDOSCOPIC DIAGNOSIS OF THORACIC DISEASE, 72
Leah M. Backhus • Aaron M. Cheng • Douglas E. Wood
- 6 ENDOSCOPIC THERAPIES FOR THORACIC DISEASES, 79
Lara W. Schaheen • James D. Luketich

PART C TRAUMA, 99

- 7 THORACIC TRAUMA, 100
Todd C. Crawford • Clinton D. Kemp • Stephen C. Yang

PART D TRACHEA, 131

- 8 TRACHEAL LESIONS, 132
Harald C. Ott • Douglas J. Mathisen

PART E BENIGN LUNG DISEASE, 150

- 9 CONGENITAL LUNG DISEASES, 151
Raghav A. Murthy • Kemp H. Kernstine • Harold M. Burkhart • Daniel T. DeArmond

- 10 BENIGN LESIONS OF THE LUNG, 179
Doraid Jarrar • Benjamin Wei • Ayesha S. Bryant • Robert J. Cerfolio

- 11 INTERSTITIAL LUNG DISEASES, 189
Subroto Paul • Yolonda L. Colson

- 12 INFECTIOUS LUNG DISEASES, 205
John D. Mitchell

- 13 SURGERY FOR EMPHYSEMA, 227
Pamela P. Samson • Bryan Fitch Meyers

- 14 LUNG TRANSPLANTATION, 240
Lisa M. Brown • Varun Puri • G. A. Patterson

PART F LUNG CANCER, 266

- 15 SCREENING FOR LUNG CANCER: CHALLENGES FOR THE THORACIC SURGEON, 267
Brendon M. Stiles • Bradley Pua • Nasser K. Altorki

- 16 LUNG CANCER WORKUP AND STAGING, 278
Valerie W. Rusch

- 17 LUNG CANCER: SURGICAL TREATMENT, 290
Masaki Anraku • Shaf Keshavjee

- 18 LUNG CANCER: MINIMALLY INVASIVE APPROACHES, 318
Jennifer M. Hanna • Mark W. Onaitis • Thomas A. D'Amico

- 19 LUNG CANCER: MULTIMODAL THERAPY, 327
Stefan S. Kachala • David P. Mason • Sudish C. Murthy

- 20 LUNG CANCER: SURGICAL STRATEGIES FOR TUMORS INVADING THE CHEST WALL, 336
Rajeev Dhupar • Michaela Straznicka • Garrett L. Walsh

- 21 ANTERIOR APPROACH TO SUPERIOR SULCUS LESIONS, 355
Philippe G. Darteville • Sacha Mussot

PART G OTHER LUNG MALIGNANCY, 365

- 22 OTHER PRIMARY TUMORS OF THE LUNG, 366
Dustin M. Walters • David R. Jones

- 23 SECONDARY LUNG TUMORS, 383
Michael Friscia • Melissa Culligan • Joseph Friedberg

PART H**CHEST WALL, 398**

- 24 CONGENITAL CHEST WALL DEFORMITIES, 399**
Konstantinos Papadakis • Robert C. Shamberger
- 25 CHEST WALL TUMORS, 430**
Mark S. Allen
- 26 THORACIC OUTLET SYNDROME AND DORSAL SYMPATHECTOMY, 438**
Harmik J. Soukiasian • Harold C. Urschel, Jr. • Robert J. McKenna, Jr.

PART I**PLEURA, 461**

- 27 SPONTANEOUS PNEUMOTHORAX, 462**
Neal G. Moores • Karl G. Reyes • Siva Raja • David P. Mason
- 28 EMPYEMA, 467**
Yaron Perry • Philip A. Linden
- 29 CHYLOTHORAX, 476**
Gaetano Rocco
- 30 MALIGNANT PLEURAL AND PERICARDIAL EFFUSIONS, 481**
Sai Yendamuri • Chukwumere Nwogu • Todd L. Demmy
- 31 PLEURAL TUMORS, 499**
Ciaran McNamee • Jeffrey B. Velotta • David J. Sugarbaker

PART J**DIAPHRAGM, 525**

- 32 SURGERY OF THE DIAPHRAGM: A DEDUCTIVE APPROACH, 526**
Carlos E. Bravo Iñiguez • Mauricio Perez Martinez • Daniel C. Wiener • Michael T. Jaklitsch
- 33 CONGENITAL DIAPHRAGMATIC HERNIA, 543**
Dario O. Fauza • Jay M. Wilson

PART K**ESOPHAGUS—BENIGN DISEASE, 574**

- 34 ESOPHAGEAL ANATOMY AND FUNCTION, 575**
Daniel S. Oh • Tom R. DeMeester
- 35 SURGERY FOR CONGENITAL LESIONS OF THE ESOPHAGUS, 593**
A. Alfred Chahine • David Spurlock • Kurt D. Newman
- 36 SURGICAL TREATMENT OF BENIGN ESOPHAGEAL DISEASES, 607**
Thomas W. Rice • Steven S. Shay • Sigurbjorn Birgisson

PART L**ESOPHAGUS—CANCER, 644**

- 37 STAGING TECHNIQUES FOR CARCINOMA OF THE ESOPHAGUS, 645**
Virginia R. Litle

- 38 ESOPHAGEAL RESECTION AND REPLACEMENT, 657**
Cynthia S. Chin • Philip A. Linden • Ali Al-Dameh • Scott J. Swanson

- 39 MULTIMODALITY THERAPY FOR ESOPHAGEAL CANCER, 688**
Wayne L. Hofstetter • Boris Sepesi

PART M**MEDIASTINUM, 697**

- 40 MEDIASTINAL ANATOMY AND MEDIASTINOSCOPY, 698**
Pamela P. Samson • Bryan Fitch Meyers
- 41 ANTERIOR MEDIASTINAL MASSES, 711**
Chuong D. Hoang • Joseph B. Shrager
- 42 THE MIDDLE MEDIASTINUM, 724**
Christopher W. Seder • Michael J. Liptay
- 43 THE POSTERIOR MEDIASTINUM, 729**
Larry R. Kaiser
- 44 SURGICAL TREATMENT OF HYPERHIDROSIS, 745**
Daniel L. Miller • Meagan M. Miller

PART N**THE FUTURE, 751**

- 45 THE MOLECULAR BIOLOGY OF THORACIC MALIGNANCIES, 752**
Shawn S. Groth • Jonathan D'Cunha
- 46 INNOVATIVE THERAPY AND TECHNOLOGY, 769**
Valentino J. Bianco • Arjun Pennathur • James D. Luketich

SECTION 2**ADULT CARDIAC SURGERY****PART A****BASIC SCIENCE, 786**

- 47 SURGICAL ANATOMY OF THE HEART, 787**
Andrew C. Cook • Benson R. Wilcox • Robert H. Anderson
- 48 VASCULAR PHYSIOLOGY, 802**
Ashraf A. Sabe • David G. Harrison • Frank W. Sellke
- 49 PHYSIOLOGY OF THE MYOCARDIUM, 818**
R. John Solaro • Margaret V. Westfall
- 50 VENTRICULAR MECHANICS, 831**
Mark Ratcliffe • Liang Ge • Julius Guccione
- 51 BLOOD COAGULATION, TRANSFUSION, AND CONSERVATION, 851**
Jerrold H. Levy • Ian J. Welsby • Charles E. Murphy

PART B**DIAGNOSTIC PROCEDURES, 869**

- 52 CORONARY ANGIOGRAPHY: VALVE AND HEMODYNAMIC ASSESSMENT, 870**
Alexander G. Truesdell • J. Dawn Abbott
- 53 APPLICATIONS OF CARDIOVASCULAR MAGNETIC RESONANCE AND COMPUTED TOMOGRAPHY IN CARDIOVASCULAR DIAGNOSIS, 889**
Murilo Foppa • Thomas H. Hauser • Susan B. Yeon • Warren J. Manning
- 54 NUCLEAR CARDIOLOGY AND POSITRON EMISSION TOMOGRAPHY IN THE ASSESSMENT OF PATIENTS WITH CARDIOVASCULAR DISEASE, 910**
Sunit-Preet Chaudhry • Neil M. Gheewala • Brian G. Abbott
- 55 DIAGNOSTIC ECHOCARDIOGRAPHY (ULTRASOUND IMAGING IN CARDIOVASCULAR DIAGNOSIS), 927**
Rosario V. Freeman

PART C**MEDICAL- AND CATHETER-BASED TREATMENT OF CARDIOVASCULAR DISEASE, 951**

- 56 INTERVENTIONAL CARDIOLOGY, 952**
Stuart H. Chen • Duane S. Pinto
- 57 MEDICAL MANAGEMENT OF ACUTE CORONARY SYNDROMES, 973**
Robert N. Piana • Jayant Bagai
- 58 THE PHARMACOLOGIC MANAGEMENT OF HEART FAILURE, 987**
Eric H. Awtry • Wilson S. Colucci

PART D**PERIOPERATIVE AND INTRAOPERATIVE CARE OF THE CARDIAC SURGICAL PATIENT, 1008**

- 59 ANESTHESIA AND INTRAOPERATIVE CARE OF THE ADULT CARDIAC PATIENT, 1009**
Mario Montealegre-Gallegos • Khurram Owais • Feroze Mahmood • Robina Matyal
- 60 CRITICAL CARE FOR THE ADULT CARDIAC PATIENT, 1026**
Judson B. Williams • Carmelo A. Milano • Peter K. Smith
-  **61 CRITICAL CARE FOR WAR-RELATED THORACIC INJURIES, 1051**
Jeremy W. Cannon • Jeffrey D. McNeil
- 62 NEUROPSYCHOLOGIC DEFICITS AND STROKE, 1064**
John W. Hammon • David A. Stump
- 63 CARDIOPULMONARY BYPASS: TECHNIQUE AND PATHOPHYSIOLOGY, 1071**
Hadi D. Toeg • Fraser D. Rubens

- 64 DEEP STERNAL WOUND INFECTION, 1094**
Pierre Voisine • Richard Baillet • François Dagenais
- 65 MYOCARDIAL PROTECTION, 1101**
Sidney Levitsky • James D. McCully
- 66 CLINICAL QUALITY AND SAFETY IN ADULT CARDIAC SURGERY, 1125**
Nassrene Y. Elmadhun • Justine M. Carr • Frank W. Sellke

VOLUME ■ TWO**PART E****SURGICAL MANAGEMENT OF AORTIC DISEASE, 1137**

- 67 SURGERY OF THE AORTIC ROOT AND ASCENDING AORTA, 1138**
Tirone E. David
- 68 SURGERY OF THE AORTIC ARCH, 1159**
Michael Z. Tong • Lars G. Svensson
- 69 DESCENDING THORACIC AND THORACOABDOMINAL AORTIC SURGERY, 1184**
Joseph S. Coselli • Kim I. de la Cruz • Ourania Preventza • Scott A. LeMaire
- 70 TYPE A AORTIC DISSECTION, 1214**
Philippe Demers • D. Craig Miller
- 71 TYPE B AORTIC DISSECTION, 1244**
Philippe Demers • D. Craig Miller
- 72 ENDOVASCULAR THERAPY FOR THE TREATMENT OF THORACIC AORTIC PATHOLOGIES, 1260**
Prashanth Vallabhajosyula • Wilson Y. Szeto • Joseph E. Bavaria
- 73 OCCLUSIVE DISEASE OF THE BRACHIOCEPHALIC VESSELS AND MANAGEMENT OF SIMULTANEOUS SURGICAL CAROTID AND CORONARY DISEASE, 1276**
Maral Ouzounian • Scott A. LeMaire • Joseph S. Coselli
- 74 PERCUTANEOUS INTERVENTION ON ABDOMINAL AORTIC AND PERIPHERAL VASCULAR DISEASE, 1293**
Victor Chien • Elliot L. Chaikof
- 75 INJURY TO THE HEART AND GREAT VESSELS, 1307**
Peter I. Tsai • Matthew J. Wall, Jr. • Kenneth L. Mattox

PART F**SURGICAL MANAGEMENT OF VALVULAR HEART DISEASE, 1316**

- 76 VALVE REPLACEMENT THERAPY: HISTORY, VALVE TYPES, AND OPTIONS, 1317**
Afshin Ehsan • Gus J. Vlahakes
- 77 SURGICAL TREATMENT OF AORTIC VALVE DISEASE, 1334**
Talal Al-Atassi • Gebrine El Khoury • Munir Boodhwani

- 78 AORTIC VALVE REPAIR, 1350**
Munir Boodhwani • Gebrine El Khoury
- 79 TRANSCATHETER AORTIC VALVE REPLACEMENT, 1368**
Vinod H. Thourani • Sebastian Iturra • Eric L. Sarin
- 80 SURGICAL TREATMENT OF THE MITRAL VALVE, 1384**
Andrew B. Goldstone • Y. Joseph Woo
- 81 SURGICAL TREATMENT OF TRICUSPID VALVE DISEASES, 1430**
Carlos A. Mestres • Jose M. Bernal • Jose L. Pomar
- 82 NATIVE AND PROSTHETIC VALVE ENDOCARDITIS, 1457**
Amy G. Fiedler • Lawrence S. Lee • Frederick Y. Chen • Lawrence H. Cohn
- 83 ANTICOAGULATION, THROMBOSIS, AND THROMBOEMBOLISM OF PROSTHETIC CARDIAC VALVES, 1466**
Joseph C. Cleveland, Jr. • Frederick L. Grover
-  **84 ROBOTIC AND MINIMALLY INVASIVE MITRAL VALVE SURGERY, 1475**
Craig M. Jarrett • A. Marc Gillinov • Tomislav Mihaljevic

PART G

MANAGEMENT OF CARDIAC ARRHYTHMIAS, 1483

- 85 CARDIAC DEVICES FOR THE TREATMENT OF BRADYARRHYTHMIAS AND TACHYARRHYTHMIAS, 1484**
Adam S. Fein • Lilian P. Joventino • Peter J. Zimetbaum
- 86 CATHETER ABLATION OF ARRHYTHMIAS, 1509**
Ethan R. Ellis • John V. Wylie, Jr. • Mark E. Josephson
- 87 SURGICAL TREATMENT OF CARDIAC ARRHYTHMIAS, 1526**
Christopher P. Lawrance • Matthew C. Henn • Ralph J. Damiano, Jr.

PART H

SURGICAL MANAGEMENT OF CORONARY ARTERY DISEASE AND ITS COMPLICATIONS, 1550

- 88 CORONARY ARTERY BYPASS GRAFTING, 1551**
Talal Al-Atassi • Hadi D. Toeg • Vincent Chan • Marc Ruel
-  **89 OFF-PUMP CORONARY ARTERY BYPASS GRAFTING AND TRANSMYOCARDIAL LASER REVASCLARIZATION, 1589**
Jatin Anand • Ashraf A. Sabe • William E. Cohn
- 90 ROBOTIC AND ALTERNATIVE APPROACHES TO CORONARY ARTERY BYPASS GRAFTING, 1603**
Stephanie Mick • Suresh Keshavamurthy • Tomislav Mihaljevic • Johannes Bonatti

- 91 RE-DO CORONARY ARTERY BYPASS SURGERY, 1616**
Bruce W. Lytle
- 92 ISCHEMIC MITRAL REGURGITATION, 1624**
Anelechi C. Anyanwu • Javier G. Castillo • Amit Arora • David H. Adams
- 93 POSTINFARCTION VENTRICULAR SEPTAL DEFECT AND VENTRICULAR RUPTURE, 1653**
Sharven Taghavi • Abeel A. Mangi
- 94 NONATHEROSCLEROTIC CORONARY ARTERY DISEASE, 1663**
Neel R. Sodha • Roger J. Laham • Frank W. Sellke

PART I

SURGICAL MANAGEMENT OF HEART FAILURE, 1674

- 95 PERICARDIUM AND CONSTRICTIVE PERICARDITIS, 1675**
Donald D. Glower
- 96 SURGICAL MANAGEMENT OF HYPERTROPHIC CARDIOMYOPATHY, 1691**
Hartzell V. Schaff
- 97 LEFT VENTRICULAR ASSIST DEVICES AND TOTAL ARTIFICIAL HEART, 1707** 
Koji Takeda • Hiroo Takayama • Yoshifumi Naka
- 98 HEART TRANSPLANTATION, 1729**
Peter Chiu • Robert C. Robbins • Richard Ha
- 99 HEART-LUNG TRANSPLANTATION, 1757** 
Steve K. Singh • Hari R. Mallidi
- 100 LEFT VENTRICULAR RESTORATION: SURGICAL TREATMENT OF THE FAILING HEART, 1776** 
Lorenzo Menicanti • Serenella Castelvechio
- 101 REGENERATIVE CELL-BASED THERAPY FOR THE TREATMENT OF CARDIAC DISEASE, 1804**
Nick J.R. Blackburn • Aleksandra Ostojic • Erik J. Suuronen • Frank W. Sellke • Marc Ruel
- 102 SURGERY FOR PULMONARY EMBOLISM, 1827**
Patricia A. Thistlethwaite • Michael Madani • Stuart W. Jamieson
- 103 TUMORS OF THE HEART, 1849**
Oz M. Shapira • Michael J. Reardon

SECTION 3

CONGENITAL HEART SURGERY

- 104 CARDIAC EMBRYOLOGY AND GENETICS, 1861**
Amy L. Juraszek
- 105 SEGMENTAL ANATOMY, 1874**
Stephen P. Sanders

- 106** DIAGNOSTIC IMAGING: ECHOCARDIOGRAPHY AND MAGNETIC RESONANCE IMAGING, 1887
Tal Geva
- 107** CARDIAC CATHETERIZATION AND FETAL INTERVENTION, 1915
Audrey C. Marshall
- 108** SURGICAL APPROACHES AND CARDIOPULMONARY BYPASS IN PEDIATRIC CARDIAC SURGERY, 1937
Luis Quinonez • Pedro J. del Nido
- 109** SURGICAL APPROACHES, CARDIOPULMONARY BYPASS, AND MECHANICAL CIRCULATORY SUPPORT IN CHILDREN, 1966
Francis Fynn-Thompson • Ravi R. Thiagarajan • Luis Quinonez

FUNCTIONAL ANATOMY OF THE AORTIC ROOT

The aortic root is the anatomic segment between the left ventricle and the ascending aorta. It contains the aortic valve and other anatomic elements, which function as a unit. The aortic root has several anatomic components: the subcommissural triangles, the aortic annulus, the aortic cusps, the aortic sinuses or sinuses of Valsalva, and the sinotubular junction.

The subcommissural triangles are part of the left ventricular outflow tract, but they play an important role in the function of the aortic valve. The subcommissural triangles of the noncoronary aortic cusp are fibrous extension of the intervalvular fibrous body and membranous septum, whereas the subcommissural triangle beneath the left and the right aortic cusps is an extension of the muscular interventricular septum (Fig. 67-1). The aortic annulus, a fibrous structure with a scalloped shape, attaches the aortic valve to the left ventricle. It is attached directly to the myocardium in approximately 45% of its circumference, and to fibrous structures in the remaining

55%. Histologic examination of the aortic annulus reveals that the aortic root has a fibrous continuity with the anterior leaflet of the mitral valve and membranous septum, and it is attached to the muscular interventricular septum by fibrous strands (Fig. 67-2). An important structure immediately below the membranous septum is the bundle of His. The atrioventricular node lies in the floor of the right atrium between the tricuspid annulus and the coronary sinus orifice. This node gives origin to the bundle of His, which travels through the right fibrous trigone along the posterior edge of the membranous septum to the muscular interventricular septum. At this point, the bundle of His divides into left and right bundle branches, which run subendocardially along both sides of the interventricular septum.

The normal aortic valve has three cusps. Each cusp has a semilunar shape and has a base and a free margin. The base is attached to the aortic annulus in a crescent fashion. The point at which the free margin of a cusp joins its base is the commissure, and the ridge in the aortic wall that lies immediately above the commissures is the sinotubular junction. The spaces contained between the aortic annulus and the sinotubular junction are the

FIGURE 67-1 ■ The inside of the aortic root.

FIGURE 67-2 ■ Microphotograph of the aortic annulus, cusps, and sinuses.

aortic sinuses, or sinuses of Valsalva. There are three cusps and three sinuses: left cusp and sinus, right cusp and sinus, and noncoronary cusp and sinus. The left main coronary artery arises from the left aortic sinus, and the right coronary artery arises from the right aortic sinus.

The normal aortic root has a fairly consistent shape, and the sizes of the cusps, the aortic annulus, the aortic sinuses, and the sinotubular junction are somewhat interdependent.¹⁻⁴ Thus, large cusps have a proportionally large annulus, sinus, and sinotubular junction. The three aortic cusps often have different sizes in a person, and the right and noncoronary cusps are usually larger than the left cusp.³ The same cusp may have different sizes in individuals with the same body surface area.^{3,4} There are, however, certain geometric parameters that are fairly constant among the various components of the aortic root, and this knowledge is indispensable to understanding the principles of aortic valve repair or replacement with stentless biological valves.

The free margin of an aortic cusp extends from one of its commissures to the other. The length of the free margin of an aortic cusp is approximately 1.5 times the length of its base (Fig. 67-3). During diastole, the free margins and part of the body of the three cusps touch each other approximately in the center of the aortic root to seal the aortic orifice. Thus, the average length of the free margins of three aortic cusps must exceed the diameter of the sinotubular junction to allow the cusps to coapt centrally and render the aortic valve competent. If a pathologic process causes shortening of the length of the free margin of a cusp, or if the sinotubular junction dilates, the cusps cannot coapt centrally, resulting in aortic insufficiency (Fig. 67-4). If the length of a free margin is elongated, the cusp prolapses, and depending on the degree of prolapse, aortic insufficiency ensues (Fig. 67-5).

The diameter of the aortic annulus is 10% to 20% larger than the diameter of the sinotubular junction of the aortic root in young patients (see Fig. 67-3). As the number of elastic fibers in the arterial wall decreases with age, the sinotubular junction dilates, and its diameter tends to become equal to that of the aortic annulus in older patients.

Dilation of the aortic annulus pulls the belly of the aortic cusps apart, decreasing the coaptation area, and it

FIGURE 67-3 ■ Geometric relationship between the free margin (FM) and base of the aortic cusps, sinotubular junction (STJ), and aortic annulus (AA).

eventually causes aortic insufficiency (Fig. 67-6). With dilation of the aortic annulus, the subcommissural triangles of the noncoronary cusp tend to become more obtuse as the crescent shape of the aortic annulus along its fibrous insertion flattens (see Fig. 67-6). The subcommissural triangle beneath the right and left cusps does not change much in patients with annuloaortic ectasia, because it is part of the muscular interventricular septum and is not affected by the connective tissue disorder that causes dilation of the fibrous skeleton of the heart.

The aortic sinuses facilitate closure of the aortic valve by creating eddies and currents between the cusps and arterial wall (Fig. 67-7). They also prevent the cusps from

occluding the coronary artery orifices during systole, thus guaranteeing myocardial perfusion during the entire cardiac cycle. Isolated dilation of the aortic sinuses does not cause aortic insufficiency.⁵

The aortic root of young individuals is elastic and very compliant. It expands and contracts during the cardiac cycle. Expansion and contraction of the aortic annulus are heterogeneous, probably because of its attachments to contractile myocardium and to fibrous structures such as the membranous septum and intervalvular fibrous body. On the other hand, the expansion and contraction of the sinotubular junction are more uniform. The aortic root also displays some degree of torsion during isovolumic contraction and ejection of the left ventricle.⁶ Compliance decreases with aging because of loss of elastic fibers, and the movements of the aortic annulus, cusps, sinuses, and sinotubular junction also change.

PATHOLOGY OF THE AORTIC ROOT AND ASCENDING AORTA

The wall of the aorta is composed of three layers: intima, media, and adventitia. The intima is a thin layer of ground substance lined by endothelium, and it is easily traumatized. The media is the thickest of the three layers, and it is made of elastic fibers arranged in spiral fashion to increase the tensile strength. The adventitia is a thin, fibrous layer and contains the vasa vasorum, which carries the nutrients to the media. The aorta is highly compliant, and it expands and contracts during the cardiac cycle because of the elastic fibers in the media. Compliance decreases with aging because of fragmentation of the elastic fibers and an increase in the amount of fibrous tissue in the media. Hypertension, hypercholesterolemia, and coronary artery disease cause premature aging of the aorta.⁷⁻⁹ Exercise seems to protect the elasticity of the aorta.⁸

Degenerative diseases of the media with aneurysm formation are the most common disorders of the aortic root

FIGURE 67-4 ■ Dilation of the sinotubular junction causes aortic insufficiency.

FIGURE 67-5 ■ Elongation of the free margin of an aortic cusp causes prolapse with resulting aortic insufficiency.

and ascending aorta. A broad spectrum of pathologic and clinical entities is grouped under degenerative disorders, ranging from severe degeneration of the media, which can become clinically important early in life in cases such as Marfan syndrome in children, to cases of the not so important mild dilation of the ascending aorta in older adults. Bicuspid and unicuspid aortic valve diseases are often associated with dilation of the aorta. Atherosclerosis, infectious and noninfectious aortitis, and trauma are other pathologic entities with which the cardiac surgeon must be familiar. Primary tumors of the aortic root and ascending aorta are rare. False aneurysms and aortic root abscess are problems commonly encountered in clinical practice.

Degenerative Aneurysms of the Proximal Aorta

Degenerative aneurysms of the thoracic aorta in older patients are often related to risk factors such as smoking, hypertension, and hyperlipidemia. In young patients without risk factors, the explanation for aneurysm

formation is on a genetic basis. Genetic aneurysms of the aorta can be classified into three main groups:

1. Inherited syndromes predisposing to early onset of aortic aneurysms, such as Marfan syndrome, Loeys-Dietz syndrome, and aneurysm-osteoarthritis syndrome
2. Familial aneurysms
3. Sporadic aneurysms including young patients without family history of aneurysm

Aneurysms of the proximal aorta are often caused by cystic medial degeneration (cystic medial necrosis). Histologically, necrosis and disappearance of muscle cells in the elastic lamina, and cystic spaces filled with mucoid material are often observed. Although these changes occur more often in the proximal aorta, they can affect any portion or the entire aorta. These changes weaken the arterial wall, which dilates and forms a fusiform aneurysm. The aortic root may be involved in this pathologic process, and in patients with Marfan syndrome, the aneurysm usually begins in the aortic sinuses. Patients with aortic root aneurysms are usually in their second or third decade of life when the diagnosis is made. Other patients have relatively normal aortic roots but develop ascending aortic aneurysms. These patients are usually in their fifth or sixth decade of life. Finally, certain patients have extensive degenerative disease of the entire aorta and develop the so-called mega-aorta syndrome with dilation of the thoracic and abdominal aorta.

Ascending aortic aneurysms tend to increase in size and eventually rupture or cause aortic dissection. The transverse diameter of the aneurysm is the most important predictor of rupture or dissection. In a study by Coady and associates¹⁰ of 370 patients with thoracic aneurysms (201 ascending aortic aneurysms), during a mean follow-up of 29.4 months, the incidence of acute dissection or rupture was 8.8% for aneurysms smaller than 4 cm, 9.5% for aneurysms of 4 to 4.9 cm, 17.8% for 5 to 5.9 cm, and 27.9% for those larger than 6 cm. The median size of the ascending aortic aneurysm at the time of rupture or dissection was 5.9 cm.

The growth rates of thoracic aneurysms are exponential.¹⁰ In the study by Coady and associates,¹⁰ the growth rate ranged from 0.08 cm/yr for small (<4 cm) aneurysms to 0.16 cm/yr for large (8 cm) aneurysms. The growth rates for chronic dissecting aneurysms were much higher than for chronic nondissecting aneurysms. Other studies found greater annual growth rates than did the Coady group.^{11,12} In addition, the growth rates for aortic root aneurysms may be different from those of ascending aortic aneurysms.

Most patients with aortic root or ascending aortic aneurysms are asymptomatic, and the aneurysm is usually found during routine chest radiographs, which show a widened mediastinum.¹³ Tracheal and esophageal displacement may be observed in the posterolateral view of the chest radiographs. Approximately one third of the patients complain of vague chest pain.¹³ In patients with a massive ascending aortic aneurysm, signs of superior vena cava obstruction may be present. If aortic insufficiency is present, there may be cardiac enlargement and the physical findings associated with it. The diagnoses of aortic root and ascending aortic aneurysm can be confirmed with echocardiography.

Transesophageal echocardiography is the best diagnostic tool to study aortic root aneurysm and the mechanism of aortic insufficiency. The echocardiographer should obtain information on each component of the aortic root, and particularly the aortic cusps. The number of cusps, their thickness, the appearance of free margins, and the excursion of each cusp during the cardiac cycle must be observed carefully. The coaptation areas of the cusps should also be investigated in multiple views, and Doppler imaging should be recorded. Information regarding the morphologic features of the aortic sinuses, sinotubular junction, and ascending aorta is also important. The diameters of the aortic annulus, aortic sinuses, sinotubular junction, and ascending aorta should be obtained in multiple views. The lengths of the free margins of the cusps should be estimated if possible. The mechanism of aortic insufficiency can often be determined with transesophageal echocardiography. Dilation of the sinotubular junction is a common cause of aortic insufficiency in patients with ascending aortic aneurysm and normal aortic cusps. Dilation of the aortic annulus and of the sinotubular junction is usually the cause of aortic insufficiency in patients with aortic root aneurysm. Although fenestrations in the cusps are not easily seen with echocardiography, a regurgitant jet in a commissural area is suggestive of fenestration.

Computed tomography (CT) with intravenous contrast enhancement permits accurate evaluation of the extent and size of the aneurysm. Three-dimensional imaging techniques can provide additional information on the extensiveness and type of aneurysm (e.g., fusiform or saccular).

Magnetic resonance imaging (MRI) provides even more information than CT scanning because it visualizes the arterial wall and surrounding structures with greater contrast. In addition, it has been increasingly used in the diagnosis and management of patients with heart diseases.¹⁴ Magnetic resonance angiography is replacing contrast angiography.¹⁵

Inherited Aneurysms of the Proximal Aorta

Marfan Syndrome

Marfan syndrome is an autosomal dominant, variably penetrant, inherited disorder of the connective tissue in which cardiovascular, skeletal, ocular, and other abnormalities may be present to variable degrees. The prevalence is estimated to be approximately 1 in 5000 individuals. It is caused by mutations in the gene that encodes fibrillin-1 (*FBNI*) on chromosome 15. This is a large gene (approximately 10,000 nucleotides in the messenger RNA), and identification of the mutation is a complex task. More than 1000 mutations in *FBNI* have been identified. The phenotype is highly variable because of varying genotype expression.

The clinical features of Marfan syndrome were thought to be caused by weaker connective tissues resulting from defects in *FBNI*, a glycoprotein and principal component of the extracellular matrix microfibril. This concept was inadequate to explain the overgrowth of long bones, osteopenia, reduced muscular mass and adiposity, and craniofacial abnormalities often seen in Marfan syndrome.¹⁶ Dietz and colleagues^{16,17} showed in experimental mice with Marfan syndrome that many findings are the result of abnormal levels of activation of transforming growth factor β (TGF- β), a potent stimulator of inflammation, fibrosis, and activation of certain matrix metalloproteinases, especially matrix metalloproteinases 2 and 9. Excess TGF- β activation in tissues correlates with failure of lung septation, development of a myxomatous mitral valve, and aortic root dilation in mice.¹⁸ This combination of structural microfibril matrix abnormality, dysregulation of matrix homeostasis mediated by excess TGF- β , and abnormal cell-matrix interactions is responsible for the phenotypic features of Marfan syndrome.¹⁶⁻¹⁸ Ongoing destruction of the elastic and collagen lamellae and medial degeneration result in progressive dilation of the aortic root, as well as in a predisposition to aortic dissection from the loss of appropriate medial layer support. Loss of elasticity in the media causes increased aortic stiffness and decreased distensibility.¹⁹

The main features of Marfan syndrome include disproportionate long bone overgrowth, ectopia lentis and aortic root aneurysm. Diagnosis is not always simple, and a multidisciplinary approach is needed to diagnose and manage patients with this autosomal dominant disorder. In 1996, a panel of experts developed the "Ghent criteria" for the diagnosis of Marfan syndrome.²⁰ Table 67-1 shows the original Ghent criteria, which contain a set of "major" and "minor" manifestations in various organs including cardiovascular, ocular, skeletal, pulmonary, dura mater, and skin.²⁰ The presence of major criteria in two separate systems and involvement of a third (minor or major) was needed to establish the diagnosis of Marfan syndrome.²⁰ Using these criteria, a high proportion of patients diagnosed as Marfan are found to have *FBNI* mutations. However, some manifestations contained in the Ghent criteria are age dependent, and there are patients with skeletal abnormalities and ectopia lentis without aortic root aneurysm, even in the presence of

TABLE 67-1 Diagnostic Criteria for Marfan Syndrome*

System	Major Criteria	Minor Criteria
Family history	Independent diagnosis in parent, child, sibling	None
Genetics	Mutation in <i>FBN1</i>	None
Cardiovascular	Aortic root dilation Dissection of ascending aorta	Mitral valve prolapse Calcification of the mitral valve (age < 40 yr) Dilation of the pulmonary artery Dilation or dissection of the descending aorta
Ocular	Ectopia lentis	Two needed: Flat cornea Myopia Elongated globe
Skeletal	Pectus excavatum needing surgery Pectus carinatum Pes planus Wrist and thumb sign Scoliosis > 20 degrees or spondylolisthesis Arm span–height ratio > 1.05 Protrusio acetabula (radiograph, MRI) Diminished extension elbows (<170 degrees)	Two major or one major and two minor signs: Moderate pectus excavatum High, narrowly arched palate Typical facies Joint hypermobility
Pulmonary	—	Spontaneous pneumothorax Apical bullae
Skin	—	Unexplained stretch marks (striae) Recurrent or incisional hernia
Central nervous	Lumbosacral dural ectasia (CT or MRI)	—

*The presence of major criteria in two separate systems and involvement of a third (minor or major) are needed to establish the diagnosis of Marfan syndrome.

CT, Computed tomography; MRI, magnetic resonance imaging.

BOX 67-1 Revised Ghent Criteria for the Diagnosis of Marfan Syndrome

IN THE ABSENCE OF FAMILY HISTORY

1. Aortic root dilation ($Z > 2$) or dissection and ectopia lentis = Marfan
2. Aortic root dilation ($Z > 2$) or dissection and *FBN1* mutation = Marfan
3. Aortic root dilation ($Z > 2$) or dissection and systemic score ≥ 7 points = Marfan
4. Ectopia lentis and *FBN1* known to associated aortic root dilation/dissection

IN THE PRESENCE OF FAMILY HISTORY

5. Ectopia lentis and family history of Marfan
6. Systemic score (≥ 7 points) and family history of Marfan
7. Aortic root dilation ($Z \geq 2$ in >20 years of age; $Z \geq 3$ in <20 years of age) and family history of Marfan

From Loeys BL, Dietz HC, Braverman AC, et al: The revised nosology for the Marfan syndrome. *J Med Genet* 47:476–485, 2010.

FBN1 mutations. Experts in this area got together again and developed a “Revised Ghent Nosology for the Marfan Syndrome” (Box 67-1) which emphasizes aortic root aneurysm, ascending aortic dissection and ectopia lentis.²¹

The most common cardiovascular features of Marfan syndrome are aortic root aneurysm and mitral valve prolapse. These anatomic abnormalities may cause aortic rupture, aortic dissection, aortic insufficiency, and mitral insufficiency.

Mitral valve prolapse is age dependent and is more common in women. It is caused by myxomatous

degeneration of the mitral valve apparatus, which is present in up to 80% of patients with Marfan syndrome, but only 25% of them develop mitral insufficiency. The posterior mitral annulus is grossly dilated in patients with mitral insufficiency, and it is often displaced posteriorly.²² The mitral annulus can also become heavily calcified and display a horseshoe appearance on radiographs.

The dilation of the aortic root is often progressive, and the rate of expansion, which varies somewhat, is usually less than 1 or 2 mm/yr. Shores and colleagues¹² randomized 70 patients with Marfan syndrome into propranolol-treated and placebo groups. The growth rates of the aortic root aneurysms in untreated patients were slightly more than three times those of patients who received β -adrenergic blockage. This study has been the scientific basis to treat these patients with a β -blocker agent. Calcium antagonists and angiotension-converting enzymes have also been reported as effective in delaying aortic dilation, but at present, β -blocker remains the drug of choice.²³ A prospective randomized clinical trial showed that losartan is effective in reducing the rate of aortic root dilation in patients with Marfan syndrome, and it reduces the rate of dilation of the arch after aortic root replacement.²⁴ The combination of losartan with a β -blocker was more effective in preventing dilation of the aortic root than β -blocker alone in a small, randomized trial in children.²⁵

Aortic dissection is rare in patients with aortic root aneurysm of less than 50 mm, unless they have a family history of aortic dissection.²⁶ The dissection in most patients starts at the level of the sinotubular junction (Stanford type A aortic dissection). Surgery of the aortic root is recommended when the transverse diameter of the aortic sinuses reaches 50 mm. In patients with family

history of dissection, surgery should be considered when the diameter reaches 45 mm. Without surgery, most patients with Marfan syndrome die in their third decade, from complications of aortic root aneurysm such as rupture, aortic dissection, or aortic insufficiency.^{27,28} In approximately 10% of patients, the dissection starts just beyond the left subclavian artery (Stanford type B aortic dissection).

Patients with Marfan syndrome should be followed at regular time intervals. Doppler echocardiography is the best diagnostic tool for monitoring changes in the mitral valve and aortic root. Patients with an aortic root greater than 40 mm should be followed with echocardiographic measurements twice yearly. MRI of the remaining thoracic and abdominal aorta should also be used when indicated.

Pregnancy in women with Marfan syndrome has two potential problems: the risk of having a child who will inherit the disorder and the risk of acute aortic dissection during the third trimester, parturition, or the first postpartum month. Offspring have a 50% risk of inheriting the syndrome. The risk of aortic dissection is less known, but it appears to be low in patients with normal aortic root and cardiac function.²⁹

Loeys-Dietz Syndrome

Mutations in the genes encoding TGF- β receptors 1 and 2 have been found in association with a continuum of clinical features. On the mild end is a presentation similar to that of the Marfan syndrome, or familial thoracic aneurysm and dissection,^{30,31} and on the severe end, there is a complex phenotype in which aortic dissection or rupture commonly occurs in childhood.³² This complex phenotype is characterized by the triad of hypertelorism, bifid uvula (or cleft palate), and generalized arterial tortuosity with widespread vascular aneurysm and dissection. This phenotype has been classified as Loeys-Dietz syndrome.³² Affected patients have a high risk of aortic dissection or rupture at an early age and at relatively small aortic diameters. CT angiograms should be obtained from the head to the pelvis. Surgery is recommended for adults when the aortic root exceeds 4 cm or the descending thoracic aorta exceeds 5 cm. If the craniofacial features are severe in children, surgery is recommended when the aortic root z-score is greater than 3, or when the expansion is greater than 0.5 cm in 1 year.³³

Ehlers-Danlos Syndrome

The Ehlers-Danlos syndrome encompasses a group of heterogeneous connective tissue disorders that involve the skin and joints and cause hyperelasticity and fragility of the former and hypermobility of the latter. It can also involve the cardiovascular system. Vascular Ehlers-Danlos syndrome is a rare autosomal dominant inherited disorder of the connective tissue resulting from mutation of the *COL3A1* gene encoding type III collagen.³⁴ Afflicted individuals are prone to serious vascular, intestinal, and obstetric complications. These problems are rare during infancy but occur in up to 25% of affected persons before the age of 20 years and in 80% before the

age of 40. Median survival is 48 years. Spontaneous rupture without dissection of large- and medium-caliber arteries, such as the abdominal aorta and its branches, the branches of the aortic arch, and the large arteries of the limbs accounts for most deaths. Intestinal perforation, usually involving the colon, is less often fatal. Pregnancy is a high risk for women with this syndrome. Aortic root dilation was present in 28% in a series of 71 patients with Ehlers-Danlos syndrome.³⁵ Aortic dissection is uncommon.

As with many rare diseases, delayed or incorrect diagnosis can lead to inadequate or inappropriate management. Diagnosis is based on clinical findings, including specific facial features, thin translucent skin, propensity to bleeding, and rupture of vessels or viscera. Diagnosis can be confirmed by biochemical assays showing qualitative or quantitative abnormalities in type III collagen secretion, or by molecular biology studies demonstrating mutation of the *COL3A1* gene. Varied molecular mechanisms have been observed with different mutations in each family. No correlation has been established between genotype and phenotype. Diagnosis should be suggested in any young person with arterial or visceral rupture or colonic perforation. There is currently no specific treatment for this syndrome.

Bicuspid Aortic Valve Disease

Congenital aortic valve malformations include a phenotypic continuum of unicuspid valves (severe form), the various types of bicuspid aortic valves (moderate form), tricuspid valves (normal), and the rare quadricuspid valves.³⁶

Bicuspid aortic valve, the most common of these malformations, occurs in 1% to 2% of the population. Movahed and colleagues³⁷ recently reviewed 24,265 patients who had echocardiograms performed for various clinical reasons, and 1742 echocardiograms obtained by screening teenage athletes in Southern California, and found a prevalence of bicuspid aortic valves of 0.6% in the large cohort and 0.5% in the smaller one. Males are affected more than females at a ratio of 4:1. There is a relatively high incidence of familial clustering, which suggests an autosomal dominant inheritance with reduced penetrance^{38,39}; however, it remains unproved that bicuspid aortic valve is an inherited disorder. Patients with bicuspid aortic valve usually have three aortic sinuses and two cusps of different sizes. The larger cusp, usually the one attached to the interventricular septum, contains a raphe, which probably represents an incomplete commissure. The raphe extends from the mid portion of the cusp to the aortic annulus, and its insertion in the aortic root is at a lower level than the other two commissures. Bicuspid aortic valves with two cusps and two sinuses are uncommon and called "type 0"; the most common type is with one raphe and is called "type 1," and finally with two raphes is "type 2."⁴⁰ Types 1 and 2 can be subclassified according to the fused cusps: left-right is the most common form (a raphe in between the left and right cusps). Abnormal origin of the coronary arteries and circumflex artery dominance are common in patients with bicuspid aortic valve.⁴¹

Normally functioning bicuspid aortic valves may last the patient's lifetime. Others become stenotic by the fourth or fifth decade of life. Aortic insufficiency can also occur, and it is often associated with dilated aortic annulus.⁴² It is more common in younger patients, and it results from the prolapse of one cusp, usually the one that contains the raphe.

Both bicuspid and unicuspid aortic valves are often associated with premature degenerative changes in the media of the wall of the aortic root and ascending aorta.^{43,44} These patients are at risk of developing chronic degenerative aneurysms of the ascending aorta and type A aortic dissection.⁴⁵

Atherosclerosis

Atherosclerosis of the ascending aorta and transverse arch is a common cause of stroke.^{46,47} Sometimes, atherosclerosis can cause extensive calcification of the aortic root, ascending aorta, and transverse arch, which is often associated with coronary artery disease, stenosis of one or both coronary arteries orifices, and aortic valve stenosis. Extensive calcification of the ascending aorta is clinically described as "porcelain" aorta.^{48,49} Atherosclerotic aneurysms of the ascending aorta are uncommon; they are more common in the abdominal aorta and to a lesser degree in the descending thoracic aorta. Atherosclerosis often causes irregular and saccular aneurysms of the ascending aorta rather than the more fusiform shape of those caused by degenerative disease of the media.

Infectious Aneurysms

Syphilis was a common cause of aneurysm of the ascending aorta, but it is now rare. The spirochetal infection destroys the muscular and elastic fibers of the media, which are replaced by fibrous and other inflammatory tissues. The ascending aorta is the most common site of involvement, and the aneurysm is usually saccular.⁵⁰ The wall of the ascending aorta is frequently calcified. Syphilitic aortitis also causes coronary ostial stenosis and aortic valve insufficiency.⁵⁰ Although rare, other bacteria can also cause aneurysm of the ascending aorta.

Aortitis

Various types of aortitis can involve the ascending aorta.⁵¹⁻⁵⁶ Giant cell arteritis is among the more common, and it involves medium-sized arteries, but the aorta and its branches are involved in approximately 15% of cases.⁵⁵ The etiology of aortitis, also called *temporal arteritis*, is unknown. The characteristic lesion is a granulomatous inflammation of the media of large- and medium-caliber arteries, such as the temporal artery. Narrowing of the aorta is rare. Occasionally, the inflammatory process weakens the aorta, leading to aneurysm formation, aortoannular ectasia, and aortic insufficiency.⁵⁴ Patients are usually older than 50 years, with a mean age of 67 years, and most are women. Diagnosis is established by biopsy of the involved artery, usually the temporal artery.

Takayasu arteritis is a chronic inflammatory disease that often involves the aortic arch and its major branches.

The pulmonary artery may also be involved. The lesions are purely stenotic in 85% of patients, aneurysmal in 2%, and mixed in 13%.^{52,53} Aortic insufficiency occurs in approximately 25% of the cases. It has been classified as type I when the aortic arch is involved, type II when the arch is free of disease but the thoracoabdominal aorta and its branches are affected, type III when both areas are affected, and type IV when the pulmonary artery is involved.^{53,56} The etiology is unknown, but it is probably an autoimmune disorder. It occurs worldwide, but most cases are seen in Asia and Africa. The disease affects women more than men at a ratio of 8:1.^{51,53} The mean age at the time of the diagnosis is 29 years.

Ankylosing spondylitis, Reiter syndrome, psoriatic arthritis, and polyarteritis nodosa can cause aortic insufficiency because of annuloaortic ectasia. Behçet disease can cause aneurysm of the ascending aorta.

Aortic Dissection

Aortic dissections are discussed in [Chapters 70](#) and [71](#).

Ascending Aorta Tumors

Primary tumors of the ascending aorta are extremely rare. Most aortic tumors are located in the descending thoracic or abdominal aorta, and they are usually sarcomas.^{57,58}

Ascending Aorta Trauma

Nonpenetrating traumatic injuries of the ascending aorta are often fatal and diagnosed at autopsy.⁵⁹ The penetrating trauma is usually a bullet or stab wound, and it causes cardiac tamponade when the intrapericardial portion of the aorta is involved. These injuries are frequently fatal.

SURGICAL TREATMENT OF ASCENDING AORTIC ANEURYSM

Although ascending aortic aneurysms may be isolated lesions, more often they are associated with aortic valve disease. Both bicuspid and tricuspid aortic valve diseases may be associated with degenerative aneurysms of the ascending aorta, but bicuspid aortic valve disease appears to be associated with premature degeneration of the media of the aorta.

Ascending aortic aneurysm can cause aortic insufficiency in patients with anatomically normal aortic valve cusps if the sinotubular junction becomes dilated (see [Fig. 67-4](#)). These patients can develop symptoms related to the aortic insufficiency, but more often the aneurysm is asymptomatic and is discovered during a routine chest radiograph or echocardiogram as part of the workup for an unrelated problem. Surgery should be considered when the transverse diameter of the ascending aorta exceeds 55 mm.⁶⁰ If there is moderate or severe aortic insufficiency, the aortic valve cusps are normal by echocardiography, and the valve is judged to be repairable, then operation is justifiable when the ascending aorta reaches 50 mm in diameter.⁶¹ If the aneurysm is

associated with a genetic syndrome, surgery should be considered when the diameter reaches 50 mm.⁶⁰ If associated with a normally functioning bicuspid aortic valve, surgery is recommended when the diameter reaches 55 mm.^{60a}

Operative Techniques

Surgery for ascending aortic aneurysm is performed using cardiopulmonary bypass, which is established by cannulating the transverse aortic arch, right axillary artery or femoral artery, and the right atrium. In patients with bicuspid aortic valve the aneurysm frequently extends up to the innominate artery and a brief period of circulatory arrest is necessary to resect the proximal arch and perform the distal anastomosis. The proximal anastomosis should be performed at the level of the sinotubular junction. The Dacron graft used to replace the ascending aorta should not be too long or too large. When the ascending aorta expands to develop an aneurysm, it also becomes elongated. Thus, during its

replacement, the graft should be much shorter than the aneurysm. In fact, a graft of 4 to 6 cm in length is all that is needed to replace the entire ascending aorta from sinotubular junction to the level of the innominate artery. Longer grafts can kink and cause partial obstruction and even hemolysis. A single graft can be used, but it should be beveled at the distal anastomosis, and its shorter side should be aligned with the medial part of the arch (Fig. 67-8). The diameter of the graft should be between 24 and 32 mm, depending on the patient's body surface area. When the diameter of the graft used is larger than the diameter of the sinotubular junction by more than a couple of millimeters, its caliber should be reduced to that of the sinotubular junction at the level of the anastomosis. This is easily done by plication of that end of the graft. Matching the diameter of the graft to that of the sinotubular junction is important to prevent late development of aortic insufficiency.

If the aortic valve is incompetent but the aortic cusps are normal and the sinotubular junction is dilated, all that is needed to reestablish valve competence is to reduce the

FIGURE 67-8 ■ Replacement of the ascending aorta for aneurysm.

diameter of the sinotubular junction to allow the cusps to coapt again. The ascending aorta is transected 5 mm above the sinotubular junction. All three commissures are pulled upward and approximate to each other until the cusps coapt centrally. The diameter of an imaginary circle that contains all three commissures is the correct diameter of the sinotubular junction. A graft of that diameter is then sutured to the remnants of ascending aorta wall at the level of the sinotubular junction. Because the aortic cusps are frequently of different sizes, the spaces between the commissures should reflect that during performance of the proximal anastomosis. Aortic valve competence can be assessed by injecting cardioplegia solution under pressure in the graft and observing the left ventricle for distention. In our group, we prefer to use two separate segments of grafts when aortic valve repair is necessary and the entire ascending aorta or transverse arch, or both, need replacement. We usually do the distal anastomosis first (under hypothermic circulatory arrest) and work on the aortic valve during rewarming of the patient. The distal and proximal grafts are trimmed and sutured to one another (Fig. 67-9).

If the noncoronary aortic sinus is aneurysmal, it should be replaced along with the ascending aorta. This is accomplished by selecting a graft of an appropriate diameter, as previously described, and then creating a neo-aortic sinus in one of its ends. The width of the neo-aortic sinus is equal to the distance between the commissures of the cusp, and the height is approximately equal to the diameter of the graft. This neo-aortic sinus is sutured directly to the remnant of arterial wall and aortic annulus (Fig. 67-10).

Sometimes one aortic cusp is slightly elongated, and its free margin coapts at a level lower than the other two cusps. The free margin can be shortened by plication of the central portion along the nodule of Arantius (Fig. 67-11). If the free margin is elongated and thinned or has a fenestration near a commissure, it can be reinforced

with a double layer of a 6-0 expanded polytetrafluoroethylene suture (Fig. 67-12).

Patients with a normally functioning bicuspid aortic valve, normal aortic root, and ascending aortic aneurysm can be treated with simple replacement of the ascending aorta.

Patients with aortic valve disease that is not amenable to repair and an ascending aortic aneurysm are treated with aortic valve replacement and supracoronary replacement of the ascending aorta. If only the noncoronary aortic sinus is dilated, aortic valve replacement of the ascending aorta with a graft extension into the noncoronary sinus (see Fig. 67-10) is preferable to composite

FIGURE 67-9 ■ Replacement of the ascending aorta with adjustment of the diameter of the sinotubular junction.

FIGURE 67-10 ■ Replacement of the ascending aorta and noncoronary aortic sinus.

FIGURE 67-11 ■ Repair of aortic cusp prolapse by shortening its free margin.

FIGURE 67-12 ■ Reinforcement of the free margin of the aortic cusp with a double layer of a 6-0 expanded polytetrafluoroethylene suture.

replacement of the aortic valve and ascending aorta with reimplantation of the coronary arteries. If two aortic sinuses are dilated, composite replacement of the aortic valve and ascending aorta with reimplantation of the coronary arteries should be performed as described for aortic root aneurysm.

Clinical Outcomes

Isolated replacement of the ascending aorta for chronic aneurysm is uncommon.^{61,62} Patients with ascending aortic aneurysm often have aortic insufficiency or aortic valve disease that may also need surgical attention. Whether the operation is performed in isolation or combined with other procedures, the operative mortality for elective surgery is low.⁶¹⁻⁶⁴ In our experience with 103 patients who had aortic valve-sparing operations for ascending aortic aneurysm and aortic insufficiency, only one patient died perioperatively.⁶¹ We reviewed our experience with aortic valve replacement and supracoronary replacement of the ascending aorta at Toronto General Hospital during a 12-year interval and identified 132 patients.⁶⁴ There were six operative deaths, and the series included acute aortic dissections, acute infective endocarditis, and reoperations.⁶⁴ Cohn and colleagues⁶² also reported a low operative mortality for replacement of the ascending aorta. The operative mortality for ascending aortic surgery has decreased over the past four decades.⁶⁵

Age, functional class, and associated diseases play an important role in the operative risk.

The long-term survival of our 103 patients who had aortic valve-sparing operations for ascending aortic aneurysm and aortic insufficiency was only 54% at 10 years, but most of them had extensive vascular disease including transverse aortic arch disease or mega-aorta syndrome.⁶¹ Our patients who had aortic valve replacement and supracoronary replacement of the ascending aorta had a 10-year survival of 70%, but they were younger than those who had aortic valve repair and had less extensive vascular disease.⁶⁴

Patients who had replacement of the ascending aorta with or without aortic valve surgery must be evaluated annually with echocardiography to assess the size of the retained aortic root and the function of the aortic valve; they should also have CT scans or MRI of the remaining thoracic and abdominal aorta. Aneurysms of the aortic root, false aneurysms, valve dysfunction, and infections in the graft or aortic valve are problems that can develop and need surgical treatment.⁶⁶

Patients who had aortic valve repair or replacement with bioprosthetic valves do not need anticoagulation if they are in sinus rhythm. Two recent retrospective observational studies in older patients with bioprosthetic aortic valves suggested that anticoagulation during the first 6 months was associated with a survival benefit, but there was a higher risk of bleeding.^{67,68} Our clinical experience does not support that, and we continue to recommend aspirin only for these patients.⁶⁹ Replacement of the ascending aorta with a tubular Dacron graft appears to have no effect on the durability of bioprosthetic heart valves.⁷⁰ Patients with mechanical valves should be anticoagulated with warfarin sodium.

SURGICAL TREATMENT OF AORTIC ROOT ANEURYSMS

Patients with Marfan syndrome and other genetically linked aortic root aneurysm should be considered for surgery when the transverse diameter of the aortic sinuses reaches 50 mm.⁶⁶ In Loeys-Dietz syndrome, the threshold is 42 mm.⁶⁶ In older patients without a known aortic genetic link, it may be appropriate to wait until the root reaches 55 mm,⁶⁶ unless the cusps are normal and an aortic valve sparing is feasible, in which case 50 mm is reasonable. As mentioned before, if there is family history of dissection, surgery should be considered at an earlier stage of dilation of the aortic root.

The aortic cusps are often normal or minimally stretched when the indication for surgery is the diameter of the aortic sinuses and an aortic valve sparing operation should be performed.^{66,71} If the cusps are abnormal, composite replacement of the aortic valve and ascending aorta with reimplantation of the coronary arteries should be performed.⁷²

Operative Techniques

The two basic types of aortic valve-sparing operations for patients with aortic root aneurysms are remodeling

of the aortic root and reimplantation of the aortic valve.^{66,71}

Remodeling of the Aortic Root

The aortic root is dissected circumferentially down to the level of the aortic annulus, and the three aortic sinuses are excised, leaving approximately 5 mm of tissue attached to the aortic annulus and around the coronary artery orifices. The three commissures are gently suspended upward and are approximated until the three cusps coapt. The diameter of an imaginary circle that includes all three commissures is approximately the diameter of the tubular Dacron graft to be used for reconstruction of the aortic sinuses (Fig. 67-13). One of the ends of this graft is tailored to create neo-aortic sinuses. The widths of the neo-aortic sinuses are based on the distance between commissures of each cusp when they are pulled upward to determine the diameter of the graft. The heights of the neo-aortic sinuses should be approximately equal to their width. The three commissures are secured on the outside of the graft immediately above the neo-aortic sinuses, and the remnants of aortic wall and aortic annulus are sutured to the neo-aortic sinuses with a continuous 4-0 polypropylene (see Fig. 67-13). The coronary arteries are reimplanted into their respective sinuses. If an aortic cusp coapts at a level lower than the other two, shortening of the free margin corrects the problem (see Figs. 67-11 and 67-12).

FIGURE 67-13 ■ Aortic valve-sparing operation: remodeling of the aortic root.

Reimplantation of the Aortic Valve

The aortic root is dissected circumferentially to a level immediately below the aortic annulus. This is not possible beneath the commissure between right and non-coronary aortic cusps, and it should be stopped where the right ventricle and atrium are attached to the root. Next, multiple 2-0 or 3-0 polyester sutures with Teflon felt pledgets are passed from the inside to the outside of the left ventricular outflow tract through a single horizontal plane corresponding to the lowest portion of the aortic annulus along its fibrous components and following the scalloped shape of the annulus along its muscular component and slightly less so along the membranous septum to avoid the bundle of His (Fig. 67-14). The diameter of the sinotubular junction is estimated by pulling the three commissures upward until the cusps coapt. A tubular Dacron graft 4 to 6 mm larger than the diameter of the sinotubular junction is selected, and a small triangular excision is made in one of its ends and the remaining portion is plicated in two or three places to reduce its

diameter by 2 to 4 mm depending on the diameter of the aortic annulus. Most grafts that we currently use are 28 to 34 mm in diameter, depending on the size of the patient and the aortic cusps. The sutures passed through the left ventricular outflow tract are then passed from the inside to the outside of the tailored end of the graft. If reduction in diameter of the aortic annulus is desirable, it is done beneath the commissures of the noncoronary cusp. This is accomplished by placing the sutures closer in the graft than they are beneath the commissures of the noncoronary cusp. The aortic valve is placed inside the graft and all sutures are tied on the outside. The spatial distribution of these sutures is important to prevent tears or distortion of the aortic annulus. The three commissures are suspended inside the graft and secured to it with 4-0 polypropylene sutures with Teflon felt pledgets. These sutures are then used to secure the aortic annulus and remnants of the aortic sinuses to the graft. The coronary arteries are reimplanted into their respective sinuses. The spaces between commissures are plicated to create a slight bulge in the neoaortic sinuses and to reduce the diameter of the graft to that of the desirable sinotubular junction. Cusp prolapse or reinforcement of the free margin with fine Gore-Tex sutures can be done if needed (see Figs. 67-11 and 67-12).

Patients with a normally functioning bicuspid aortic valve and aortic root aneurysm are also candidates for aortic valve-sparing operations.

There is a commercially available Dacron graft with neo-sinuses of Valsalva.⁷³ Some surgeons who have wide experience with aortic valve sparing procedures have used the "Valsalva graft" for aortic valve reimplantation.⁷⁴ We have not used it because we believe that it deforms the aortic annulus, which normally evolves along a single horizontal plane. If the aortic annulus is correctly resuspended into the Valsalva graft, the annulus plane changes from a horizontal to a curved shape. This may compromise the durability of the repair.

Aortic Root Replacement

Replacement of the aortic root is performed when the aortic cusps are abnormal and cannot be safely repaired.^{63,64} The aortic cusps are excised and the coronary arteries detached from their sinuses with 5 or 6 mm of aortic sinus wall around them. A valved conduit is then used to replace the aortic root. This conduit can be a commercially available Dacron tube with a mechanical valve already attached to one of its ends. The valved conduit is sutured to the aortic annulus, and the coronary arteries are reimplanted into the graft (Fig. 67-15).

An aortic homograft or a xenograft can also be used for aortic root replacement. It is not wise to use a pulmonary autograft for replacement of the aortic root in patients with aortic root aneurysms, because the pulmonary autograft may become aneurysmal when subjected to systemic pressures. Finally, aortic root replacement also can be performed with a conduit prepared in the operating room. When a stented bioprosthetic valve is desirable, the bioprosthesis and the Dacron tube can be secured to the aortic annulus using the same sutures. Another method is to secure the bioprosthetic valve

FIGURE 67-14 ■ Aortic valve sparing operation: reimplantation of the aortic valve.

FIGURE 67-15 ■ Composite replacement of the ascending aorta and aortic valve with a stentless porcine aortic root.

inside a tubular Dacron graft 1 cm from one of its ends and secure the Dacron graft alone to the annulus (Fig. 67-16). This approach allows aortic valve re-replacement without taking down the original graft or the coronary arteries when the bioprosthetic valve fails. The technique of securing a tubular Dacron graft in the left ventricular outflow tract before implanting a prosthetic valve into it is very useful when there is, for example, a narrow or destroyed aortic annulus resulting from multiple previous operations, calcification, or endocarditis. The Dacron graft can be tailored to conform to the anatomy of the left ventricular outflow tract before it is sutured to it.⁷⁵

In the original description of aortic root replacement by Bentall and DeBono in 1968,⁷² the aneurysm was opened and a tubular Teflon graft containing a mechanical valve was sutured to the aortic annulus, to the coronary arteries (by suturing the graft to the aortic sinus wall around their orifices), and to the distal aorta. The aneurysm wall was wrapped around the graft and closed tightly for hemostasis. Pseudoaneurysm formation at the coronary artery and the aortic anastomoses was a complication of this technique.⁷⁶ To decompress the space between the graft and aneurysm wall, Cabrol and colleagues⁷⁷ described the creation of a shunt between that space and the right atrium. Kouchoukos and coworkers⁷⁶ stressed the importance of not wrapping the graft with the aneurysm wall to avoid tension on the anastomoses when accumulation of blood occurs between the aneurysmal wall and the graft. They recommended an open technique in which the coronary arteries are detached from the aortic sinuses and sutured to the tubular Dacron

FIGURE 67-16 ■ Composite replacement of the ascending aorta and aortic valve with a bioprosthetic valve.

graft.⁷⁶ Cabrol and colleagues⁷⁸ described another technique whereby the two coronary arteries were connected to each other with a smaller graft and anastomosed side to side with the valved conduit. This technique, however, has not provided long-term results that were as good as direct coronary artery reimplantation.⁷⁹

Clinical Outcomes

Surgery for aortic root aneurysm is associated with low operative mortality and morbidity, particularly when performed electively. In a report of our experience with aortic valve sparing operations, there were only three operative deaths among 220 patients operated for aortic root aneurysms, including 24 with acute type A aortic dissection.⁸⁰ Other series showed similarly low operative mortality rates.^{74,81-83} Long-term outcomes of aortic valve sparing operations have been excellent.⁸¹⁻⁸⁴ We recently reported our experience with aortic valve sparing operations for aortic root aneurysm in 371 patients.⁸⁵ Their mean age was 47 ± 15 years, 78% were men, 35.5% had Marfan syndrome, 12% had type A aortic dissection, and 9% had bicuspid aortic valves. Approximately one half of the patients had moderate or severe aortic insufficiency before surgery. The technique of remodeling of the aortic root was used in 75 patients and the reimplantation of the aortic valve in 226. There were 4 operative and 35 late deaths. Patients' survival at 18 years was 76.8% and

approximately 10% lower than that of the general population matched for age and gender. Ten patients required reoperation on the aortic valve (5 reimplantation and 5 remodeling) for aortic insufficiency in 8 and infective endocarditis in 2. One valve was re-repaired and 9 replaced; all patients survived reoperation. The freedom from reoperation on the aortic valve at 18 years was 94.8%. Eighteen patients developed moderate or severe aortic insufficiency (12 reimplantation and 6 remodeling). Overall freedom from moderate or severe aortic insufficiency at 18 years was 78% and similar for both types of aortic valve sparing operations. These findings suggest that aortic valve sparing operations provide excellent long-term outcomes, but there is evidence of gradual deterioration in aortic valve function during the first two decades of follow-up. Patients with Marfan syndrome and other inherited aortic root aneurysms seem to have a more stable aortic valve function after reimplantation of the aortic root than after remodeling of the aortic root.^{86,87} Kerchov and colleagues⁸⁸ have shown that this is also true with incompetent bicuspid aortic valves which frequently have dilated aortic annulus.

The principal cause of early failure after aortic valve sparing operations is technical errors,⁸⁹ probably because of unrecognized cusp prolapse after reconstruction of the aortic root.

It remains unknown whether aortic valve sparing operations offer a survival benefit over aortic valve replacement with either biological or mechanical valves. Comparative studies suggest similar outcomes, but most studies contain series with relatively short-term follow-up because aortic valve sparing operations are relatively new in comparison with aortic root replacement.

Aortic root replacement with valved conduit is probably more frequently performed than aortic valve sparing operations during surgical treatment of aortic root aneurysm. In a report by Gott and coworkers⁹⁰ on the outcomes of aortic root surgery in patients with Marfan syndrome operated on at 10 experienced surgical centers, the operative mortality was 1.5% among 455 patients who had elective surgery, 2.6% among 117 who had urgent surgery, and 11.7% among 103 who had emergency surgery, mostly for acute aortic dissection. However, in the experience of Gott and colleagues at the Johns Hopkins Hospital,⁹¹ there was no operative death among 235 patients who had elective surgery and only two deaths among 36 who had urgent or emergent surgery. In our personal experience with 105 patients with Marfan syndrome in whom 44 had root replacement and 61 had aortic valve sparing, there was only one operative death, which occurred in a patient who was in preoperative cardiogenic shock because of end-stage aortic insufficiency.⁹² Patients with Marfan syndrome are usually young when they require aortic root surgery, which is one reason the operative mortality is low. Surgery in older patients is associated with higher risk.^{79,93} Age and clinical presentation are important determinants of outcome.^{63,79,93,94} Surgery in patients with acute type A aortic dissection is associated with higher operative and late mortality (see Chapter 70). Overall, the operative mortality for aortic root replacement is around 5% to 10%.^{63,64,79,93,94}

The long-term survival after aortic root replacement in patients with Marfan syndrome is very good. Gott and associates⁹⁰ reported from multiple institutions that the 10-year survival after aortic root surgery ranged from 60% to 80%, depending on the clinical presentation, but the 10-year survival was 81% in their experience at Johns Hopkins.⁹¹

An unresolved problem with patients with inherited aortic root aneurysms is the risk of aortic dissection late after repair of the aortic root, regardless of the technique used to repair the aortic root.^{74,81,84,90,91,95}

Thromboembolism, hemorrhage, and endocarditis remain problems for patients who have aortic root replacement with mechanical valves,^{79,90,92,93} and tissue degeneration and reoperation are problems for those who have a biological aortic valve.⁹²

Patients who have aortic root replacement require periodic checkups including a transthoracic echocardiogram and CT scans or MRI of the residual aorta. Patients with Marfan syndrome should receive a β -blocker after repair of the aortic root aneurysm.

Reoperations in the aortic root after replacement with valved conduits can be difficult, but in the hands of experts it can be done with relatively low operative mortality.^{75,96,97} When the problem is graft infection, the use of an aortic homograft is believed to offer the patient the best chance of cure.^{98,99} We and others have obtained similar results by using an approach of radical resection of infected tissues and reconstruction with synthetic grafts.¹⁰⁰⁻¹⁰²

ROSS PROCEDURE

The Ross procedure is a complex operation whereby the diseased aortic valve is replaced with the patient's own normal pulmonary valve, and a biological valve, usually a pulmonary homograft, is used to replace the pulmonary valve. This operation was first described in the experimental laboratory by Lower and colleagues¹⁰³ in 1960 and clinically performed by Ross in 1967.¹⁰⁴ The original technique consisted of implanting the pulmonary autograft inside the aortic root in a subcoronary position. For the next two decades, Donald Ross was practically the only surgeon performing this procedure.¹⁰⁵ Interest in this operation increased after the initial report by Stelzer and colleagues¹⁰⁶ in the late 1980s, who performed it using the technique of aortic root replacement, a more reproducible method.

The Ross procedure is ideal for children because the pulmonary autograft grows with the child.¹⁰⁷ Although the Ross procedure can be used in patients of any age,¹⁰⁸ most surgeons prefer to use it in children and young adults.^{109,110} Some surgeons consider it ideal for treating patients with active infective endocarditis.¹¹¹ The Ross procedure also has been performed in patients with dilated ascending aorta or even aneurysms.¹¹² It should not be used in patients with known genetic disorders of the proximal aorta or in patients with connective tissue disorders.

Although the Ross procedure was developed almost five decades ago, it gained popularity only in the 1990s.

According to the Society of Thoracic Surgeons Database, its peak usage in adults was in 1998 with 1.2% of all isolated aortic valve replacements; its use declined steadily to 0.09% in 2010.¹¹³

Operative Techniques

The three basic methods to transfer the pulmonary autograft into the aortic position are subcoronary implantation, aortic root replacement, and aortic root inclusion.

Subcoronary Implantation

The aortic valve should be exposed through a transverse aortotomy 1 cm above the sinotubular junction. The diseased aortic valve is excised, and all calcified tissues are completely débrided from the aortic annulus, membranous septum, and anterior leaflet of the mitral valve. The diameters of the aortic annulus and sinotubular junction are measured with a metric sizer. The pulmonary artery is opened just before its bifurcation, and the valve cusps are inspected. If the cusps are normal, the pulmonary root is excised. The incision in the right ventricular outflow tract is made along a single horizontal plane approximately 3 mm below the lowest level of the pulmonary annulus. Care must be exercised to prevent damage to the left anterior descending artery and the first septal perforator branch. It is difficult to measure the diameter of the pulmonary annulus because it is entirely attached to distensible muscle, but it can be estimated by measuring the diameter of the sinotubular junction of the pulmonary root. The diameter of the pulmonary annulus is 15% to 20% larger than the diameter of the sinotubular junction. If the diameters of the aortic annulus and sinotubular junction of the two roots are similar, the technique of subcoronary implantation will work well. If there is mismatch in size, an alternative technique should be used, and the difference in diameters should be corrected.¹¹⁴ When the pulmonary annulus is slightly larger than the aortic annulus, it can be reduced by placing the sutures beneath the subcommissural triangles close together in the left ventricular outflow tract rather than in the pulmonary autograft. The smallest pulmonary sinus (usually the posterior sinus) should be oriented toward the left aortic sinus. The pulmonary autograft is secured to the left ventricular outflow tract and aortic annulus with multiple interrupted 4-0 polyester sutures. All sutures must be distributed precisely along a single horizontal plane at the level where the pulmonary annulus coincides with the level of the aortic annulus. We agree with Yacoub and colleagues,¹¹⁵ who believe that it is important to excise the muscle beneath the commissures of the pulmonary autograft before implanting it into the left ventricular outflow tract. This makes it easier to place the pulmonary annulus to the same level of slightly below the level of the aortic annulus. One has to be meticulous about the spatial distribution of the three subcommissural spaces and maintenance of the normal scallop-shaped pulmonary annulus. Once the inflow suture line is completed, the three commissures are precisely suspended in the aortic root, and stay sutures through both arterial walls are placed immediately above the commissures. The sinuses of the

pulmonary autograft that face the left and right coronary arteries are partially excised and sutured to the aortic sinuses around the coronary artery orifices with a continuous 6-0 or 5-0 polypropylene suture. The sinus of the pulmonary autograft that faces the noncoronary aortic sinus need not be excised, and it is sutured to the aortic root at the level of the sinotubular junction. It is important not to alter the diameter of the sinotubular junction of the pulmonary autograft when it is being sutured to the aortic root or when the aortotomy is closed. The right side of the heart is reconstructed with a pulmonary homograft. This homograft should be larger than the pulmonary autograft. [Figure 67-17](#) illustrates the technique of subcoronary implantation.

Aortic Root Replacement

Aortic root replacement with a pulmonary autograft is performed as described previously for aortic root aneurysm. The aortic valve is excised and so are the sinuses, leaving 5 mm of arterial wall around the coronary artery orifices. The same steps described previously are used to harvest the pulmonary autograft and measure it. If the aortic annulus is larger than the pulmonary annulus, a reduction annuloplasty is necessary. This can be accomplished by closing the subcommissural triangles of the noncoronary sinus of the aortic root ([Fig. 67-18](#)). The pulmonary autograft is secured to the left ventricular outflow tract with simple multiple interrupted 4-0 polyester sutures along a single horizontal plane. A strip of Teflon felt in this suture line improves hemostasis and may prevent annular dilation. The coronary arteries are reimplanted into the respective sinuses. The pulmonary autograft is sutured to the ascending aorta. If the ascending aorta is dilated, it may need replacement or plication ([Fig. 67-19](#)). A strip of Dacron fabric or Teflon felt along this anastomosis prevents late dilation of the sinotubular junction.¹¹⁶

Aortic Root Inclusion

Another method of implanting the pulmonary autograft is the aortic root inclusion technique. The noncoronary aortic sinus should be incised vertically toward the aortic annulus to enhance exposure of the aortic root. The pulmonary autograft is secured to the aortic annulus using the technique described previously. After suturing the pulmonary autograft in the left ventricular outflow tract, the three commissures are pulled gently upward to determine the positions of the right and left coronary artery orifices in the pulmonary autograft. Small openings (5 or 6 mm in diameter) are made in the pulmonary autograft sinuses that correspond to the coronary artery orifices. The arterial wall of the pulmonary sinus is then sutured to the aortic sinus around the coronary artery orifices with a continuous 6-0 polypropylene suture. The three commissures of the pulmonary autograft are also sutured to the aortic wall, and the aortotomy is closed, including the aortic and pulmonary arterial walls. The incision made in the noncoronary sinus of the aortic root should be closed only if there is no bleeding between the two roots and if closure causes no distortion of the pulmonary

FIGURE 67-19 ■ The Ross procedure: aortic root inclusion.

autograft after unclamping the aorta. Figure 67-19 illustrates the technique of aortic root inclusion.

Clinical Outcomes

Despite its technical complexity, the operative mortality associated with the Ross procedure is reportedly low in centers with large experience.^{108-110,117-119} However, in the STS Database the risk adjusted operative mortality for the Ross procedure was higher than for isolated aortic valve replacement in adults.¹¹³ The main problem with the Ross procedure is that it can potentially transform a patient with isolated aortic valve disease to one with both aortic and pulmonary valve disease and even coronary artery disease, because they may undergo reimplantation if the technique of aortic root replacement is used. Early aortic insufficiency is usually due to technical errors.¹¹⁴ Thromboembolic complications are rare because of the nature of the valves used and the patients' ages. Once the pulmonary autograft is healed in the aortic root, it should not be the source of thrombus. We have documented a few episodes of transient ischemic attacks during the first few weeks after surgery, but seldom after 2 or 3 months. The risk of infective endocarditis is also very low, and when it happens it is usually in the pulmonary homograft.¹¹⁹ Subaortic false aneurysm is rare, but it may occur during the first postoperative year.¹¹⁹ Long-term survival after the Ross procedure is excellent and in some series appears to be similar to that of the general population.¹¹⁷⁻¹¹⁹

Patients who had the Ross procedure should have annual Doppler echocardiography to assess the function of the neo-aortic valve and pulmonary homograft, and to measure the size of the aortic root. The early development of aortic insufficiency is usually the result of technical problems,¹¹⁴ and late aortic insufficiency is caused by dilation or degeneration of the pulmonary autograft.^{109,110,117-119} Dilation of the aortic root is less common after the subcoronary and aortic root inclusion techniques than after aortic root replacement.¹¹⁸⁻¹¹⁹ Preoperative aortic insufficiency and dilated aortic annulus (≥ 15 mm/m²) are predictors of aortic insufficiency.^{110,118-121} Aneurysms of the sinuses of the pulmonary autograft have been described; if the pulmonary cusps remain normal, an aortic valve sparing operation is feasible.^{120,121}

We recently published our experience in a cohort of 212 patients followed prospectively with periodic assessment of valve function, and the freedom from reoperation for any reason in the pulmonary autograft was 93% at 15 years and 81.8% at 20 years.¹¹⁹ Other investigators have reported similar results^{117,118,122} and some reported worse outcomes.^{109,110} In series by Mokhles and colleagues,¹⁰⁹ the freedom from reoperation on the pulmonary autograft was 51% at 18 years. The reasons for these differences in failure rates are unclear. Pathology of the aortic valve, patient age, operative technique, and surgeon experience can all play a role.¹¹⁹

Many surgeons believe that patients who have aortic root replacement with pulmonary autograft should be treated with a β -blocker or angiotensin-converting enzyme inhibitor, or both, during the first postoperative year to prevent dilation during the adaptation of the graft

to systemic pressures, but there are no scientific data to support this treatment.

Another problem with the Ross procedure is dysfunction of the biological valve used to reconstruct the right ventricular outflow tract. A pulmonary homograft is probably the best conduit to use, but it is not free from complications, and a number of patients develop stenosis, insufficiency or both.^{109,118-119} In our series, eight patients have required reintervention for a freedom from reoperation of 92.7% at 20 years.¹¹⁹ When the homograft fails, percutaneous deployment of a stented tissue valve is often feasible, and the results are good.¹⁰⁸

The usefulness of the Ross procedure remains controversial, but we believe that it is an excellent valve for women during child-bearing years and for young adults who are physically active.

OUTCOMES

SUMMARY

The history of cardioaortic surgery has been replete with new techniques for ascending and aortic arch repairs since 1956, when Denton Cooley and Michael DeBakey replaced the ascending aorta with a homograft using cardiac bypass.^{1,2} In 1957, DeBakey and colleagues first described aortic arch replacement using antegrade brain perfusion.³ Before this, one of the few successful ascending aortic repairs was reported in 1932 by Blalock, who repaired a stab wound of the ascending aorta caused by an ice pick.⁴ By removing the occluding clot, Blalock noted the “bright red blood that shot over the screen at the head of the table on the anesthetist’s clothes.” Using only nitrous oxide and oxygen for anesthesia in a patient with cardiac tamponade most likely contributed to the hypertension and description of the procedure.

With the advent of cardiopulmonary bypass, many technical problems of aortic arch surgery were largely overcome. In 1950, Bigelow first published the results of his experiments in dogs using deep hypothermia for cardiovascular operations without cardiopulmonary bypass.⁴ Nonetheless, it was not until 1963 that Barnard combined deep hypothermia with circulatory arrest and cardiopulmonary bypass for aortic arch operations and dissection.⁵ In 1964, Borst reported using deep hypothermia and circulatory arrest to repair an arteriovenous fistula between the innominate vein and the aorta caused by shrapnel.⁴ The routine use of deep hypothermia and circulatory arrest did not, however, become popular until 1975, when Griep reported a series of aortic arch replacements using deep hypothermia and circulatory arrest.⁴ In 1983, Borst

and colleagues^{6,7} and others⁸ reported replacing the aortic arch and leaving a tube graft lying free in the descending aorta, which they called the elephant trunk technique. In 1990, Crawford and Svensson^{4,9} reported replacement of the entire aorta as a staged procedure using a modified elephant trunk technique. The modification of inverting the graft into the descending aorta while sewing the distal anastomosis resulted in a more secure anastomosis with less risk of bleeding or rupture. Subsequently, in 1993, Svensson and colleagues⁴ successfully replaced the entire aorta from the aortic valve to the aortic bifurcation during a single operation using a combined mediastinal and thoracoabdominal incision with deep hypothermia and circulatory arrest.³

Aortic arch surgery has become relatively common and safe, with a mortality risk of 2% and a stroke risk of 2%.¹⁰ In 2012, we performed 1282 aorta operations: 1065 on the thoracic aorta and 724 on the ascending aorta and aortic arch. Our approach is discussed later. In this chapter, we discuss the potential causes of aortic arch aneurysms, the association with some pathologic entities, diagnostic workup, brain protection, perfusion methods, different operative approaches, and outcomes after aortic arch surgery.

DEFINITIONS AND CLASSIFICATION

Anatomically, the aortic arch is defined as the segment of aorta between a line at a right angle proximal to the

innominate artery origin and extending to a line drawn at a right angle distal to the origin of the left subclavian artery. Aneurysms are irreversible dilations of the aorta exceeding the normal diameter for the age and height of the patient.⁴ The exact size at which the aorta is labeled “aneurysmal” varies. Definitions vary from 1.5 times to twice the normal diameter of the aorta. For patients with Marfan syndrome, we suggest that when the cross-sectional area (in square centimeters) divided by the patient’s height (in meters) exceeds a ratio of 10, it should be considered significant and an indication that the patient requires surgical repair.¹¹ Thus, in some respect, the definition of an aneurysm is not absolute but rather refers to the significant dilation of the aorta.

Aneurysms can be divided further into aortic aneurysms without penetration through the aortic adventitia (true aneurysms) and those that penetrate through the adventitia and are contained by the surrounding tissue, which prevents exsanguination of the patient (false aneurysms).⁴ In addition, aneurysms are classified according to their likely causes: medial degenerative aneurysms (typically showing loss of elastic tissue); those related to aortic dissection; other disorders of connective tissue, particularly loss of collagen as in Ehlers-Danlos syndrome or loss of elastic tissue as in Marfan syndrome; those associated with blunt trauma; aortitis; primary aortic infections or after previous cardiovascular surgery, especially graft infection in the ascending aorta; and congenital abnormalities.⁴

We prefer the term *medial degenerative aneurysms* to *atherosclerotic aneurysms* simply because not all medial degenerative aneurysms have atherosclerosis.⁴ Furthermore, atherosclerosis does not necessarily appear to be the sole causative factor in the development of medial degenerative aneurysms. It appears that atheroma formation, fibrosis, and calcification are results of degeneration that follow the primary injurious event that caused the aneurysm.

Aneurysms can be either fusiform, showing uniform dilation, or saccular in appearance.⁴ The three most common sites for saccular aneurysms are on the lesser curve of the aortic arch, on the descending aorta, and opposite the visceral vessels.⁴ The saccular aneurysms in the aortic arch are usually related to penetrating ulcers, often with localized dissection or mycotic aneurysm formation.⁴ Fusiform aneurysms of the aortic arch are typically associated with dilation of the ascending aorta, particularly when associated with inflammatory aortitis. Medial degenerative aneurysms of the root are known as *annuloaortic ectasia*, a term coined by Cooley.⁴ This results in a flasklike or hourglass appearance of the aortic root (Erdheim deformity), which is also associated, in particular, with Marfan syndrome. For example, in patients with Marfan syndrome, initiation of aortic root dilation results early in the annuloaortic ectasia stage, and, if it is not treated, there is subsequent development of aortic root, ascending aorta, and aortic arch aneurysm formation. In fact, at this late stage, aortic dissection often precedes aortic arch aneurysm formation.

The human artery consists of five distinct layers. The first or innermost layer (the endothelial layer, which lies on a basement membrane) is known as the tunica intima.

Between the tunica intima and the tunica media is a fenestrated sheath of elastic fibers known as the internal elastic lamina. The tunica media has several layers of elastic-tissue lamellae arranged concentrically along the length of the aorta, and it forms the bulk of the aortic wall. The amount of elastic tissue decreases in amount from the sinotubular ridge as the aorta progresses down to the aortic bifurcation. In the tunica media lie smooth muscle cells and the ground substance of the aorta. The latter consists of proteoglycans. The outer third of the tunica media receives its nutrition from the vasa vasorum, lymphatics, and nerves. On the outside of the tunica media is the external elastic lamina, which separates the media from the adventitia. The tunica adventitia consists of strong, tough layers of collagen and elastic fibers. Because of its strength, this is the critical layer wherein the surgeon must suture the graft placement.⁴

No clear, systematic classification of aortic pathology appears in the literature, and different pathologists have coined various terms. We favor a definition of aortic pathology based on hematoxylin and eosin (H&E) findings and elastic tissue stains. Thus, medial degenerative disease is defined as a loss of elastic fibers, and medial necrosis as a loss of smooth muscle cells. The presence of atherosclerosis superimposed on degenerative disease is described as atherosclerotic with or without calcification. Atheroma is also frequently superimposed. Inflammatory disease is diagnosed when there is evidence of chronic inflammatory cell infiltrates. The intima and adventitia may also show various degrees of hyperplasia.⁴

CAUSATIVE AND PREDISPOSING FACTORS

Congenital Aneurysms

Congenital aneurysms of the aortic arch are extremely rare, although they may be associated with aberrant right subclavian arteries from a Kommerell diverticulum situated in either the distal aortic arch or the proximal descending aorta (Figs. 68-1 and 68-2).⁴ Similarly, aneurysms can be associated with one of two types of right-sided congenital arches. For the Felson and Palayew type I right-sided arches, a vascular ring encircles and compresses the esophagus and trachea (Fig. 68-3).¹² The distal arch and descending aorta may be aneurysmal. In patients with type II right-sided arches (Fig. 68-4), the anatomy is basically a mirror image of an aberrant right subclavian artery with a Kommerell diverticulum. Thus, an aberrant left subclavian artery comes off the right-sided descending aorta.¹² More frequently, however, the aortic arch, in association with these two varieties, is hypoplastic unless the hypoplasia is severe enough to cause aortic stenosis, and prestenosis or poststenosis aneurysm formation occurs. Coarctation of the aorta is often associated with a bicuspid valve and an ascending aortic aneurysm, but, if left untreated, it may be associated with aortic arch aneurysm formation. A history of patent ductus arteriosus or ventricular septal defect may also be noted. More rarely, adult patients who have been

FIGURE 68-1 ■ **A**, Computed tomography scan of an aortic arch aneurysm associated with an aberrant right subclavian artery that was treated by a modified elephant trunk technique. **B**, The first stage of the elephant trunk procedure was done with an anastomosis between the left subclavian artery and the aberrant right subclavian artery, and the second stage was performed with an interposition graft to the right subclavian artery. **C**, Angiogram of the completed repair. Note the tube graft to the right subclavian artery arising from the more distal part of the aortic arch.

previously operated on for an interrupted aortic arch can develop ascending and aortic arch aneurysms.⁴

Medial Degenerative Aneurysms

Medial degenerative aneurysms typically occur in older adult patients who were long-term smokers or have a long history of hypertension. If the smoking history is severe and there is presence of chronic obstructive pulmonary disease (COPD), extensive atheroma formation may also be found in the aneurysms. These types of aneurysms, with extensive atheroma and atherosclerosis formation, typically involve not only the ascending aorta and the aortic arch but also the descending and thoracoabdominal aorta. Coronary artery disease and carotid artery disease are also common associations. When the aorta is inspected, small ulcers are often observed, and these can later form penetrating ulcers that result in dissection in the medial adventitial plane or false aneurysm formation if the adventitia is penetrated.⁴ Less typically, medial degenerative aneurysms are associated with

systemic inflammatory disease and various types of arthritis or vasculitis (see Vasculitis and Aortitis, later).

Aortic Dissection

The DeBakey and Stanford classifications of aortic dissection differ, and there are also different classes of dissection (Fig. 68-5)¹³ regarding replacement of the aortic arch. The class of intimal tear also influences the aortic arch repair technique.¹³

Mycotic Aneurysms

For reasons not entirely clear, true primary mycotic aneurysms of the aorta, as described by Svensson and Crawford,⁴ have a tendency to occur either on the lesser curve of the aortic arch, with a variable extent of involvement, or opposite the visceral vessels in the abdomen. It is unclear whether this is related to the structure of the aorta or to the flow patterns that result in turbulence in these areas opposite the branches of the aorta. The typical

FIGURE 68-2 ■ **A**, Computed tomography (CT) scan from a patient with an ascending and arch aneurysm, with extensive clot formation in the aneurysm, associated with an aberrant right subclavian artery. **B**, CT scan after the repair. The repair was done from the aberrant right subclavian artery ostium, through the aortic arch, using a long “tongue” extension into the descending aorta. The ascending aorta was replaced with a composite valve graft. Note the aberrant right subclavian artery coming off the distal aorta and running posterior to the esophagus and trachea.

infective organisms are *Escherichia coli*, staphylococci, *Salmonella*, and streptococci, including *Streptococcus pneumoniae*. Other strains, however, may sometimes be detected. Some of these may be related to atherosclerotic ulcers, which initially act as a nidus for subsequent infection. Mycotic aneurysms frequently penetrate through the aortic arch wall, resulting in false aneurysms or free rupture. Osler called these aneurysms mycotic because the gray, slimy lining reminded him of fungal growth. Fungal infections in the vessel walls are, on the whole, very rare, except in patients who have had graft-related infections.⁴

Vasculitis and Aortitis

Inflammatory infiltrates of the aorta are not infrequent. In a prospective examination of histologic specimens by both H&E and elastic-tissue stains, inflammatory infiltrates were found in many of the specimens. Although these inflammatory infiltrates consist of various types of leukocytes, often associated with the diseases listed later, an associated systemic illness may be absent. This suggests that the original cause of the aortic injury was unrecognized, subsequently appearing as a medial degenerative aneurysm, with formation of atherosclerosis and calcification. Previous chest radiation for Hodgkin disease or breast malignancies may also be noted in the history. Radiation-induced vasculitis is associated with severe calcification and a porcelain aorta. A stiff left ventricle, scarred right ventricle, and fixed cardiac output increase the risk of surgery.

Inflammatory systemic diseases may result in aneurysms. For example, the development of aortitis is commonly associated with Takayasu disease (nonspecific aortoarteritis) (Fig. 68-6); giant cell arteritis (Horton disease); temporal arteritis; polymyalgia rheumatica; Behçet, Buerger, Logan, Sjögren, Reiter, or Kawasaki disease; relapsing polychondritis; systemic lupus erythematosus (often mycotic); rheumatoid arthritis; sarcoid

and ankylosing spondylitis; osteoarthritis of unknown origin; ulcerative colitis; and potentially autoimmune diseases of the thyroid, such as Hashimoto.

Histologically, Takayasu disease has panaortitis, severe intimal hyperplasia, and severe adventitial fibrosis with perivascular inflammation. In contradistinction, giant cell aortitis has inflammatory margins around areas of medial necrosis and inflammation of the media. Fibrosis and intimal hyperplasia are minimal.

Trauma

Ten percent of traumatic lesions of the aorta occur in the aortic arch. The remaining 90% occur in other segments

that are discussed in [Chapters 69](#) and [75](#). The aneurysms are most often related to tears at the hinge point of the aorta during acceleration or deceleration injuries. Thus, the usual sites of primary tears are the origin of either the innominate artery or the subclavian artery (70% to 80%), although the origin of the common carotid artery may also be involved.⁴ Although blunt trauma is the most common cause in the United States, traumatic arch injuries are more frequently caused by penetrating injuries from shrapnel or bullets or knife injuries in developing countries. With penetrating lesions, involvement of the trachea, esophagus, venous system, nerves, and vertebral column significantly complicates management.

FIGURE 68-5 ■ Aortic dissection classification. **A**, Proximal dissection: (1) involvement of the ascending aorta only; (2) ascending, aortic arch, and descending aorta involvement; and (3) arch and descending involvement. **B**, Distal dissection: (1) involvement of the descending aorta with or without the abdominal aorta; (2) penetrating aortic ulcer with descending dissection; and (3) abdominal dissection (usually iatrogenic).

Tumors of the Arch

Tumors of the aortic arch are extremely rare, but when they occur they are usually found distal to the subclavian artery. Very rarely have tumors been related to prosthetic grafts.⁴

Reoperations

Patients who have undergone previous cardiovascular surgery may require reoperation either for new aneurysm formation or for false aneurysm formation. Approximately half of all patients undergoing arch operations have had previous cardiovascular surgery. There are two typical scenarios.

The first scenario involves a patient who earlier underwent acute dissection repair and subsequently developed an aortic arch aneurysm because the aorta, weakened from the dissection, had dilated over the course of time. This situation occurs commonly in patients with Marfan syndrome. It is preferable to repair only the ascending aorta at the time of the acute dissection repair,^{4,14} first because the first priority is to save the patient's life, and second because trying to repair the aortic arch simultaneously carries a much higher mortality risk.^{4,14} Furthermore, the risk of a patient's requiring another operation after acute dissection repair is, in most cases, small.^{4,14} It is, however, important that the initial acute dissection

FIGURE 68-6 ■ Classification of Takayasu aortitis. Subtypes and their extents are depicted. (From Svensson LG, Crawford ES: *Cardiovascular and vascular diseases of the aorta*, Philadelphia, 1997, Saunders, pp 42–83.)

repair should be performed with circulatory arrest unless the dissection is a DeBakey type II. This is so that the inside of the aortic arch can be inspected and a more complete hemiarch repair can be performed at the initial operation. A tear in the aortic arch can often be repaired with pledgeted 4-0 Prolene running sutures.^{4,14} The use of biological glues may also increase the risk of recurrent aneurysms.

The second scenario for reoperation involves a patient in whom there was progression of the aneurysm formation in the aortic arch after initial ascending aorta repairs, or, at the time of the ascending aorta repair, not enough of a hemiarch was repaired, particularly when circulatory arrest was not performed.

An uncommon group of patients who require reoperations are those who form aneurysms at either the origin of the greater vessels, most typically the innominate artery, or at the site where a Carrel patch of the aorta was used for reattachment of the greater vessels. The site becomes aneurysmal and enlarges. This latter scenario should be watched for particularly in patients with Marfan, Loeys-Dietz, or Ehlers-Danlos syndrome, especially if they have suffered aortic dissection and the aorta is fragile.^{4,14,15}

Although aortic graft infections are rare in our experience, such cases are often referred to us. They require extensive débridement and repair, usually with homografts (allografts). Alternatively, if homografts are not available, rifampin-soaked Gelweave grafts can be used. We also like to put in an irrigation system with a Blake

drain infusing appropriate antibiotic depending on sensitivity or 5% Betadine in saline at 50 mL/hr over a few days. If there is a cavity, omental or muscle flaps are used to fill the space (Fig. 68-7). Patients are kept on lifelong antibiotics or, for fungal infections, fungal antimicrobials, particularly the newer, less toxic form of amphotericin B. In sick, high-risk patients, conservative approaches with either percutaneous or surgical drainage have also been reported with some success as long as the infection does not involve any suture-line, graft-enteric fistulas or involve invasive gram-negative organisms such as *Pseudomonas* or *Salmonella*.^{16,17}

Syndromes Associated with Aortic Arch Pathology

Aneurysms may form in association with genetic diseases such as Marfan syndrome, Ehlers-Danlos syndrome, Erdheim syndrome (annuloaortic ectasia), Noonan syndrome, hereditary polycystic kidney disease, osteogenesis imperfecta, and Turner syndrome.⁴

HISTORY AND PHYSICAL EXAMINATION

When patients have a potential aortic arch aneurysm, neither questioning about symptoms nor physical examination is particularly informative. During the questioning, however, any history of aortic valvular disease associated with aortic root aneurysms needs to be sought, along with any history of neurologic or neurocognitive events. Computed tomography (CT) scans or magnetic resonance imaging (MRI) studies before aortic arch surgery have shown that between 40% and 60% of patients have evidence of brain injury. In a prospective randomized study, 38% of our patients, excluding those who had strokes with residual deficits and those older than 75 years, had a neurocognitive deficit before undergoing aortic arch surgery.^{18,19}

If the aortic arch aneurysms are particularly large, hoarseness may develop, particularly if the distal aortic arch is enlarged. The reason is that the left recurrent nerve wraps around the distal aortic arch at the

FIGURE 68-7 ■ **A**, An infected ascending aorta graft after initial replacement followed by reoperation with graft insertion (done elsewhere). During the third procedure, a new composite valve graft was inserted. The left main and the right coronary arteries were reattached as buttons, and the hemiarch was replaced with a separate graft. The annulus had to be reconstructed because of extensive annular abscess. Although the organism was *Staphylococcus aureus*, the patient, on suppressive antibiotics, has continued to be free of further infection. An omental flap was swung into the chest to fill dead space. **B1**, Computed tomography scan from a patient who had undergone two previous heart operations, including a composite valve graft insertion that became infected. The patient also underwent a limited sternal débridement elsewhere but later developed an abscess under the skin and associated air in the mediastinum. **B2**, The postoperative magnetic resonance angiogram after the repair. The patient had two allografts (homografts) inserted to replace the aortic root and the aortic arch. In addition, an omental flap was swung into the chest to fill the dead space.

ligamentum arteriosum and can become stretched by the aneurysm. Dysphagia may also occur, but this is more frequent with congenital lesions (see Fig. 68-4). In 1794, Bayford called this “lusoria,” referring to the Latin term *lusus naturae* meaning “a freak of nature.” This is often described as dysphagia lusoria or arteria lusoria. Dyspnea can also be a symptom when the pulmonary artery or left bronchus is constricted.⁴

Patients may complain of occasional mid-scapular pain if the aneurysms are large, although this is associated more with enlarged descending or thoracoabdominal aorta aneurysms. With aortic dissection or a false aneurysm related to a penetrating ulcer or mycotic aneurysm, severe chest pain may be present. This may be anterior or posterior chest pain with extension into the neck (see Chapters 70 and 71).

On examination, most patients do not have any physical findings specifically related to the aortic arch aneurysm, although, when the aneurysm is large, the anterior chest wall may be pulsatile and, in the worst of circumstances, may have eroded through the sternum or manubrium, particularly if infected. An associated pulsatile mass or a fullness of the neck with a pulsatile mass in the lower neck may be present. Displacement of the arch cranially may result in tortuosity of the carotid arteries. Palpation above the clavicle on the left side, at the thoracic outlet, may reveal a pulsatile mass.

During examination, the patient's arm, neck, and head pulses should be checked, because there may be discrepancies or absent pulses related to aortic dissection or aortitis, particularly giant cell arteritis or Takayasu disease.

Preoperative Studies

In addition to routine laboratory work, preoperative investigations include pulmonary function tests, because many patients may have predisposing factors such as a smoking history, Marfan syndrome with bullae formation, obstructive lesions related to the arch aneurysms (particularly with a congenital aberrant right subclavian artery lesion) (see Fig. 68-2), and right-sided aortic arches (see Fig. 68-3). Some patients are treated for a number of years for asthma because of expiratory wheezes caused by compression of the trachea or bronchi by aneurysms.⁴

Brain MRI or CT should be performed before surgery to detect any asymptomatic infarcts or brain lesions.²⁰ Most patients undergo carotid ultrasound studies if a history of coronary artery disease, peripheral vascular disease, or left main coronary artery stenosis is present. All patients undergo echocardiography before surgery,^{21,22} and, if possible, good views of the ascending aorta and descending aorta are obtained by transesophageal echocardiography to check for atheromatous disease, as this will affect the method of cannulation for arterial inflow. All patients should also undergo cardiac catheterization to identify the presence of any coronary artery disease or valvular heart disease. If time allows, we obtain preoperative neurocognitive test results. Routine 24-hour Holter monitor examinations are included in the preoperative workup because many of these patients have cardiac

arrhythmias, most likely related to valvular heart disease, chronic hypertension, coronary artery disease, or displacement of the left ventricle and the heart downward and to the left by the aneurysm. Patients with some syndromes, such as Marfan syndrome, exhibit more frequent prolonged QT intervals. Indeed, some aneurysms enlarge not only in diameter but also in length. Arrhythmias may also be related to abnormal vagal and sympathetic innervation stimulation.

At the time of cardiac catheterization, cardiologists are requested to obtain left anterior-oblique views of the aortic arch with injection of contrast material immediately proximal to the innominate artery. This is one of the best methods for obtaining good views of the aortic arch and determining the extent of the aortic arch repair that is required, including the need for an elephant trunk procedure. In the preoperative workup, before referral, patients have usually undergone contrast CT of the chest or MRI studies. CT three-dimensional reconstruction is also useful for planning.

Aortography is no longer done in all patients because of the time needed for scheduling and because it is invasive and because the dye load, often administered the day before the surgery, could compromise renal function. The operative procedure planned is discussed with the patient. On the basis of preoperative studies, it can usually be accurately predetermined whether a hemiarch, a total arch, or a total arch plus elephant trunk procedure is necessary. Additionally, it can be ascertained whether the greater vessels require bypasses because of stenotic lesions or aneurysmal disease, particularly in association with aortic dissection.

Next, again determined from preoperative studies, a decision is made as to the site of the arterial inflow for the operation. For most patients undergoing aortic arch surgery, the right subclavian artery is preferentially used for arterial inflow. In young patients, however, who need only a hemiarch procedure, particularly for Marfan syndrome, the right femoral artery is most often used. Usually, the left femoral artery is not used in patients with aortic dissection because the dissection typically extends into the left iliac artery and, thus, the femoral artery perfusion cannula may perfuse the false lumen, resulting in a flutter-valve effect and inadequate perfusion. Similarly, the aortic arch is not used because (1) it limits the extent of the repair, (2) the cannula gets in the way of the operation, (3) aortic dissection may be precipitated, and (4) if a graft is inserted, the cannula must be repositioned, either through a side graft or directly into the new aortic graft. Occasionally, the right subclavian artery is dissected and the femoral artery or aorta is used.

CARDIOPULMONARY PERFUSION ASPECTS

When the right subclavian artery is used, the technique is similar to that previously reported and shown in Figure 68-8. In a prospective randomized study, it was thought this would be a useful means for antegrade brain perfusion.^{18,19} To do this, the innominate artery, in addition to the common carotid artery, was occluded with a balloon

FIGURE 68-8 ■ **A**, Cannulation methods for antegrade brain perfusion with a side graft attached to the right subclavian artery and balloon occlusion catheters in the innominate and common carotid arteries. If a right brachial or radial artery pressure-monitoring cannula has not been inserted, pressures can be monitored in the innominate balloon catheter and, similarly, if perfusion is carried out through the left common carotid cannula, the pressure can also be monitored. **B**, Diagram of the usual setup for retrograde brain perfusion with a cannula in the superior vena cava (SVC) that has been looped with a Y arterial line that can be run through the SVC. IVC, Inferior vena cava.

catheter. The balloon catheter in the common carotid artery allowed perfusion of the left side of the brain (see Fig. 68-8). This has proved to be a safe and effective technique.

Our preference is to attach a side graft to the subclavian artery, defined as the part of the artery proximal to the lateral edge of the first rib. The reason for this is that there are fewer branches in this area and the nerve that swings across the artery to the pectoral muscles more distally does not obstruct the view. It does, however, require that the subclavius muscle be divided with electrocautery under the clavicle. Caution should be taken that the vein is not injured during this procedure. To dissect the axillary artery more laterally, care should be taken to retract the nerves out of the way and also to not injure the arterial branches. We have found the safest and best method for obtaining perfusion of the subclavian artery is to attach an 8-mm side graft, end to side. This is sewn into position with a 5-0 Prolene suture, and any leaks are oversewn with 6-0 Prolene. This allows perfusion of the vessel, both proximally and distally, and greater flow rates. Thus, by avoiding direct cannulation of the subclavian artery, there are fewer tears and there is less difficulty in repairing the artery at the end. Also, it circumvents the problem of the cannula's being inserted too far into the subclavian artery, which could result in occlusion of the common carotid artery or inadequate flow if the cannula presses up against the innominate artery wall. In our report on 1336 circulatory arrest patients, use of a side graft in the subclavian artery reduced the risk of stroke by 40%.²³

An exception to the use of the subclavian artery, however, is that it should be avoided in patients who have had aortic dissection and when the extension of the aortic dissection is noted in the vessel (see Fig. 68-5A). In three patients in whom we used the subclavian artery, when dissection was present in the artery, two suffered postoperative strokes, probably from malperfusion related to the dissection. In patients exceeding 250 pounds, a larger 10-mm side-graft is usually used.

The graft is attached after the patient is heparinized, and a basket or coil sucker is placed in the wound to collect any leaking blood or blood that accumulates within the subclavian incision pocket. The graft is carefully de-aired and connected to a three-eighths-inch to quarter-inch perfusion connector that is then connected to the arterial line of the cardiopulmonary bypass machine.

As mentioned, when the femoral artery is used, the right femoral artery is preferable. When the femoral artery is used, care must be taken, as much as possible, to ascertain that there is no atheroma present in the arterial system that may potentially embolize with retrograde pumping through the femoral artery up to the brain. Thus, the femoral artery is avoided in older adult patients and patients with atherosclerotic disease, aneurysms of the descending thoracoabdominal and abdominal aorta, reoperations, DeBakey type I and type III aortic dissections, or extensive aortitis. Similarly, when we plan to use antegrade brain perfusion or the elephant trunk procedure (see Operative Techniques, later) or acute dissection repair, the subclavian artery is the vessel of choice.^{10,18,19}

BRAIN PROTECTION

Multiple viewpoints are held about how to best protect the brain during aortic arch surgery. The areas of consideration are the degree of hypothermia at onset of circulatory arrest, either moderate (24° to 28° C) or deep (18° to 20° C); and brain perfusion, either none, retrograde, selective antegrade through right axillary, or bilateral through right axillary and left carotid. The reasoning and some of the research that we have performed resulting in the techniques we recommend are discussed here. In summary, our findings include the following: the subclavian artery is the preferred cannulation site (see earlier discussion) and the femoral artery is less so, deep hypothermia to 20° C is preferable although moderate hypothermia at 28° C with antegrade brain perfusion may be as safe if circulatory arrest times are less than 45 minutes,²⁴⁻²⁶ electroencephalogram (EEG) silence is desirable,²⁴ antegrade or retrograde brain protection should be used although antegrade is preferable for longer circulatory arrest times (exceeding 40 minutes), long cardiopulmonary bypass times are harmful (particularly with inadequate filtration), and excessive rewarming may be harmful.²⁷⁻²⁹

Brain protection will be discussed from three aspects: (1) avoidance of doing harm during aortic arch surgery, (2) prevention of stroke, and (3) prevention of neurocognitive deficits.

Primum non nocere: First Do No Harm

Before the safe use of cardiopulmonary bypass, aortic arch operations were designed to use bypass shunts from the ascending aorta to the greater vessels to avoid using a heart-lung machine. These operations were generally limited to patients who had a normal aortic root and not extensive aneurysms, but the techniques were associated with a high incidence of stroke and death. With the advent of cardiopulmonary bypass, the operations became considerably safer. Nevertheless, attempts by Crawford and coworkers³⁰ to directly cannulate aortic arch greater vessels for perfusion of the brain during aortic arch operations were associated with a high incidence of stroke—occurring in up to one third of the patients. Their view was that this was related to injury of the greater vessels by balloon catheters and occluding clamps, or by atheroma resulting in stroke. Barnard⁵ and Borst and colleagues^{6,7} independently pioneered deep hypothermia for arch surgery; however, the technique was popularized by Griep. Deep hypothermia and circulatory arrest, without perfusion of the greater vessels, thus became popular.^{4,10,31,32} Cooley³³ and Livesay emphasized the usefulness of doing an “open” distal anastomosis.

In 1993, we reported a 10% mortality and a 7% stroke rate in a series of 656 patients with deep hypothermia and circulatory arrest alone for aortic arch operations (Fig. 68-9).³⁴ In this paper, however, we described retrograde brain perfusion (see Fig. 68-8B) in 50 patients with initial encouraging results. Our subsequent study in animals also showed promising findings.^{4,35} At that time, the consensus was that strokes were related to embolic events or

FIGURE 68-9 ■ **A**, Incidence of stroke in 656 patients undergoing deep hypothermia with circulatory arrest according to the length of time of circulatory arrest (*left column*). **B**, Relationship between circulatory arrest time and the risk of 30-day death. Note that after 65 minutes, there is an exponential increase in the risk of death. **C**, Relationship between circulatory arrest time and the risk of 30-day stroke. Note that after 40 minutes, there is an increase in the risk of stroke; however, at 60 minutes, the risk appears to decline. This is a statistical aberration because, after 60 minutes of circulatory arrest, there is a rapid increase in the risk of death and, therefore, patients could not necessarily be assessed for neurologic function. AAA, Abdominal aneurysm repair; AR, aortic valve regurgitation (in parentheses because aortic valve regurgitation was significantly associated with lower risk); CA, circulatory arrest; CPB, cardiopulmonary bypass; CVA, cerebrovascular accident (history); +Desc, with descending aorta repair at the same time; DHCA, deep hypothermia and circulatory arrest; TAA, thoracoabdominal aneurysm repair.

ongoing brain metabolism during deep hypothermia with circulatory arrest. As reports showed increasing success with retrograde perfusion of the heart during cardiac arrest, it was hoped that retrograde brain perfusion might have a protective role. Mills and Ochsner³⁶ reported using retrograde brain perfusion in a patient in whom air embolization occurred to the brain from the arterial

inflow cannula.^{10,29,37} They placed the patient on cardiopulmonary bypass with arterial blood flow into the superior vena cava to try to “retrograde flush-out” air from the arterial system. Subsequently, Lemole reported using retrograde brain perfusion for aortic arch operations.⁴ This was later popularized by Ueda.^{2,4,20} More recent studies by Griep’s group,³⁸ Okita and colleagues, and others, however, have indicated that retrograde brain perfusion may also be associated with harmful side effects, including a higher incidence of stroke or neurocognitive deficits and depression.^{10,39} It has been speculated that brain edema may be a factor. In our initial use of retrograde brain perfusion, we were careful not to exceed a perfusion pressure of between 25 and 30 cm H₂O, because we knew patients with congestive heart failure could tolerate a central venous pressure at this level. Subsequently, studies suggest that a higher perfusion pressure is needed to obtain any retrograde perfusion of the brain. Furthermore, this group demonstrated that perfusion pressures that exceed 60 cm H₂O resulted in brain edema. Retrospective studies, however, show that in comparison with historical controls, results are improved.⁴⁰ There is no doubt that this method is effective in removing embolic material from the aortic arch, including atheromatous emboli. Nevertheless, the technique may be associated with harmful side effects. In our prospective, randomized study from 2000, depression appeared more common in this group of patients, and there appeared to be no neurocognitive benefit over deep hypothermia and circulatory arrest alone. In our more recent prospective, randomized study of 121 patients undergoing total aortic arch replacement in 2012, comparing retrograde and antegrade brain perfusion for total aortic arch replacements, both in conjunction to deep hypothermic circulatory arrest, there was no difference in clinical stroke rates, radiologic evidence of stroke or neuropsychologic decline. The mortality rate of the cohort was 0.8%, and clinically detected stroke occurred at a rate of 0.8%.

Milewski also showed no difference between retrograde brain perfusion/deep hypothermic circulatory arrest and antegrade brain perfusion/moderate hypothermic circulatory arrest in terms of permanent neurologic deficit, temporary neurologic dysfunction, renal failure, or death when the circulatory arrest time is less than 45 min.⁴¹ Likewise, many recent large series and randomized clinical trials have shown the safety of moderate hypothermic circulatory arrest when used with antegrade brain perfusion for circulatory arrest times less than 45 minutes. There are advantages to moderate hypothermia: it avoids the long cooling and rewarming periods, decreases cardiopulmonary bypass times, and avoids the side effects of deep cooling, mainly coagulopathy.^{26,42-45} However, should the circulatory arrest times exceed 45 minutes because of technical difficulties or the need to perform individual head vessel anastomosis, at moderate hypothermia there is a risk of systemic ischemic injury, multiple organ failure, and injury to the spinal cord. For this reason and because the procedure is not entirely predictable, we prefer always performing circulatory arrest under deep hypothermia. Finally, for circulatory arrest durations of longer than 45 minutes, bilateral antegrade brain perfusion is advisable.

Prevention of Stroke

As our knowledge of cardiopulmonary pathophysiology improved, it became clear that most strokes after cardiac surgery were related to microemboli. Most of these emboli seem to be the result of atheromatous or calcific debris from the aorta. For most patients undergoing aortic arch surgery, other sources, such as from the left atrium in patients with chronic atrial fibrillation or transiting through an atrial septal defect, are less of a problem. Another potential source of emboli is from the descending aorta or abdominal aorta or iliac and femoral arteries during femoral artery perfusion; hence, we advocate the routine use of cannulating the right axillary artery with an 8 mm graft as our aortic inflow. We prefer the use of an 8 mm graft as opposed to direct cannulation of the axillary because we have previously shown that it decreases the incidence of stroke by 40%.⁴⁶ With modern cardiopulmonary bypass techniques, the risk of massive air embolism or pump failure that can result in strokes has been greatly lessened.^{4,47} Various techniques have been used to reduce the risk of embolic-related strokes. We have not tested every method, but early on, we established a protocol based on the level of knowledge at the time that we considered of value (Table 68-1). With reference to cardiopulmonary bypass, it appears that the following are beneficial: a centrifugal pump, arterial line filtration (at least 25 μ m), leukocyte filtration, closed-bag venous reservoir, cell saver, avoiding pump suction, and reducing cardiopulmonary bypass time. If a leukocyte filter is used, it is important to use immediate preoperative plasmapheresis to remove platelets and clotting factors from the patient, because leukocyte filters tend to remove platelets from the circulation. The platelet-rich plasma is reinfused at the end of the operation. For pH management during cardiopulmonary bypass and circulatory arrest, we favor using the alpha-stat method. In the pediatric age group, there is more convincing evidence that the pH-stat method works better. In adults, however, the alpha-stat method is generally preferred, although no prospective or randomized studies have definitively answered the question of which is best in adults. An advantage with the alpha-stat method is that the lactic acid that accumulates in the brain during circulatory arrest can, to some extent, be buffered by histamine molecules on hemoglobin.^{4,10,29,47}

We advise flooding the field with carbon dioxide so any air accumulating in the heart or the field will be displaced.⁴⁸ This includes the aortic arch so that when circulation to the brain is restarted, any potentially gaseous material is carbon dioxide rather than air. Carbon dioxide is reabsorbed approximately 25 times faster than air, reducing the risk of microcirculation obstruction related to gaseous material.

In addition to perfusion aspects and the site of cannulation, we recommend packing the patient’s head in ice because it reduces the risk that the ambient operating room temperature might raise the temperature of the patient’s head during circulatory arrest.

The usage of neuroprotective agents during circulatory arrest remains controversial. Thiopental may be useful by lowering oxygen consumption, although the

TABLE 68-1 Brain Protection Protocol

Population	Protective Measures
All patients	Electroencephalogram silence Temperatures less than 20°C Head packed in ice Mannitol prime and after arrest Alpha-stat pH control LeukoGuard filter CO ₂ flooding of field Thiopental 5 mg/kg 5 min before arrest Lidocaine 200 mg before arrest Magnesium sulfate 2 g Centrifugal pump Membrane oxygenator Closed-circuit bag venous reservoir Pre-bypass plasmapheresis Routine use of cell saver device
Patients receiving antegrade brain perfusion	Right subclavian and side graft Innominate and carotid balloon occlusion (retrograde cardioplegia balloon occlusion catheter) Pressure maintained at 40-60 mm Hg Sequential removal of catheters as arch anastomosis completed
Patients receiving retrograde brain perfusion	Superior vena cava cannula Snared below azygous vein Flow rate: 300-500 mL/min Pressure: <25-35 mm Hg

evidence on clinical benefit is inconclusive. However, there is suggestion that if thiopental is administered before circulatory arrest, it may replete the cerebral energy state before arrest and prove detrimental.⁴⁹ The usage of barbiturates has declined over the years partly because of its unavailability. In a German registry for type A dissection of over 2000 patients, only 48% of patients received a neuroprotective agent such as steroids, mannitol, or barbiturates. The stroke rates were slightly lower in patients receiving steroids versus no agents (7.1% vs. 10.6%), and usage of mannitol led to lower 30-day mortality. These results are observational and have not been shown in prospective studies.⁵⁰

In our randomized clinical trial in 2012 comparing retrograde brain perfusion to antegrade brain perfusion, only 0.8% of patients had clinically evident stroke, but 9% had showed evidence of new MRI or CT infarcts or brain tissue changes, suggesting that many infarcts are clinically silent.⁵¹ In this study, we also gave patients neurocognitive tests preoperatively and 4 to 6 months after the index procedure. For each neurocognitive test, the baseline and follow-up data were used to calculate a test-retest reliability coefficient, a reliable change index (RCI), and associated 90% confidence interval for the RCI. A patient was considered to have declined neurocognitively if he or she had two or more RCIs that fell below the lower 90% confidence limit for the respective, corrected reliable change interval. Surprisingly, there was little correlation between patients who had neurocognitive dysfunction and patients who had new radiologic evidence of stroke. In total, 14% of patients had neurocognitive deficits. Of these patients, only 18% had evidence of infarct on CT or MRI, and 56% of patients with

radiologic evidence of stroke had neurocognitive decline. From the remaining 5 patients who had radiologic evidence of stroke without neurocognitive decline, 4 had strokes located in the occipital or cerebellar areas. On multivariate analysis, neither retrograde brain perfusion nor antegrade brain perfusion was an independent predictor of neurocognitive decline, clinical stroke, or radiologic stroke. To summarize, our study showed that clinical exam for neurologic events was insensitive, MRI detects more events, and the most sensitive is neurocognitive examination, which may not detect occipital or cerebellar events.

Prevention of Neurocognitive Deficits

With improved results for aortic arch surgery and fewer complications such as strokes, interest has focused on prevention of postoperative neurocognitive deficits. As mentioned, 38% of patients in our prospective randomized study were found to have, before surgery, neurocognitive deficits.^{18,19} The reason is not entirely clear, but it may be related to silent brain injury before surgery. There is also a correlation between neurocognitive deficits and other preoperative factors such as heart failure and New York Heart Association degree of dyspnea.²⁹ This would be in keeping with the finding that patients who exhibit a greater degree of systemic cardiovascular disease experience more neurocognitive deficits. The possible reasons include inadequate brain perfusion, brain edema, other factors affecting the brain vasculature, general overall poor health, and silent ischemia and white matter injury, as we have documented. Indeed, it is our impression that patients with preoperative neurocognitive deficits do not tolerate deep hypothermia and circulatory arrest well. In a previous study of 656 patients undergoing deep hypothermia and circulatory arrest,³⁴ older patients did not tolerate circulatory arrest as well as younger patients, putting them more at risk for stroke. The same probably holds true for the risk of neurocognitive deficits, but this has not been formally studied.

The incidence of neurocognitive deficits after cardiac surgery remains controversial.^{18,19,28} So much depends on the method of defining when neurocognitive deficits occur. There are many reasons why deficits can occur (e.g., preoperative neurocognitive dysfunction or atherosclerosis of the microvasculature of the brain, similar to that affecting coronary arteries). Some large studies that have examined neurocognitive dysfunction after coronary bypass surgery have used cardiopulmonary bypass pump setups that were out of date. It is also instructive that some studies have shown no differences between off-pump and on-pump incidences of neurocognitive deficits, suggesting that other factors, such as anesthesia management, are important. Studies have also shown no differences between coronary artery bypass surgery and major abdominal aortic surgery. Indeed, there is no difference between percutaneous coronary intervention and coronary bypass operations. Patients who undergo anesthesia often have neurocognitive dysfunction after surgery despite having no obvious risk factors that cause neurologic dysfunction. In our prospective, randomized study, although over 90% of patients had neurocognitive

dysfunction 3 to 6 days after surgery, by 2 to 3 weeks only 9% had a new neurocognitive deficit, and by 6 months all had recovered.^{18,19} The entire field of neurocognitive dysfunction requires further study to determine when a deficit occurs in an individual patient and what the change in global scores for an entire group of patients means. In our prospective randomized study from 2000 (Fig. 68-10), we found that patients' IQs improved after circulatory arrest over time, which clearly is not likely! The explanation was that the patients underwent repeated IQ testing (four) and learned to do the tests over time. Nevertheless, it was gratifying to note that the patients' IQs did not deteriorate after deep hypothermia and circulatory arrest. Indeed, the practice effect on reported neurocognitive scores is difficult to compensate for. Figure 68-11 shows the serum S-100 protein value changes of each group studied.

There are many reasons for potential neurocognitive dysfunction after surgery. Anesthetic gases and pharmacologic agents, including barbiturates, are factors. Other potential reasons are brain edema and swelling from third-space fluid accumulation. Undoubtedly, chemical and metabolite accumulation also play a role. Microemboli, in the form of small fat globules, or air or carbon dioxide gaseous emboli, may also be a factor.

It was once thought that emboli to the frontal lobes were largely silent and that there was selective streaming of emboli, including platelet aggregates, to the middle cerebral artery, resulting in middle cerebral artery territory infarcts. A study was done using radioactive platelet aggregates in a baboon model to test this theory.⁵² We found injection of the platelet aggregates into the left atrium resulted in equal distribution across the brain, including occipital lobes and distribution to the eye, as expected from an anatomic point of view. Injection into the common carotid arteries had a similar effect, although

the occipital lobes were spared. Injection into the internal carotid artery did not reveal any preferential streaming into the middle cerebral artery. From this we infer that the emboli to the frontal lobes do cause infarcts of equal frequency, although these may be more silent in the sense that critical motor and sensory functions are not affected. We do, however, believe that these so-called silent infarcts affect neurocognitive function, as expected from a more recent understanding of brain pathophysiology. Some neurocognitive decline after cardiopulmonary bypass may thus be related to microemboli to the frontal lobes and infarction. This is an evolving field, and the correlation between microembolic phenomena and postoperative neurocognitive function needs to be further defined. For example, it is unclear how high-intensity transient Doppler signals, produced by aortic valve prostheses, affect neurocognitive function both early and in the long term. Studies in patients with various types of aortic valve prostheses suggest that many of these are gaseous microemboli, but that they are usually transient and rapidly return into solution without causing permanent brain dysfunction.^{10,53}

In our 2000 prospective randomized study, we failed to show any benefit from antegrade or retrograde brain perfusion regarding neurocognitive function when compared with deep hypothermia with circulatory arrest alone. However, the circulatory arrest was relatively short, and for hemiarch repairs, antegrade brain perfusion resulted in significantly longer circulatory arrest time because of the time required to insert the common carotid artery catheter and the innominate artery catheter and then to work around them. For total arch replacement, there were no differences in circulatory arrest times. Retrograde brain perfusion was associated with slightly longer circulatory arrest times compared with circulatory arrest alone, probably because retrograde brain perfusion results in blood

FIGURE 68-10 ■ A, Illustration of Shipley IQ (Shiqiq) scores over time in patients who underwent deep hypothermia with circulatory arrest (dhca), retrograde brain perfusion (rbp), antegrade brain perfusion (ante), and coronary artery bypass (cab). The first tests were done preoperatively (1m), then 3 to 6 days after surgery (2m), 2 to 3 weeks after surgery (3m), and 6 months after surgery (4m).

FIGURE 68-11 ■ Relationship of time point during operation to the serum S-100 protein value. Graphed curves: ANTE, Antegrade brain perfusion; CA, all circulatory arrest patients; CAB, coronary artery bypass; DHCA, deep hypothermia and circulatory arrest alone; RBP, retrograde brain perfusion. accumulating in the operative field, which obscures the field when suturing. If we expect atheroma in the aorta at the time of surgery, and if the patient may require endarterectomy, we use antegrade perfusion via the right subclavian artery (as discussed) or retrograde brain perfusion to flush out embolic material.^{18,19}

When patients are undergoing total arch replacement and the circulatory arrest time may exceed 30 to 40 minutes, antegrade or retrograde brain perfusion is used for the repair. Data in the pediatric cardiac surgical literature show that, as with pulmonary embolectomy in adults for thrombotic material, circulatory arrest with intermittent periods of brain perfusion followed by circulatory arrest is better than one long period of circulatory arrest. For one patient undergoing a fourth complex cardiac reoperation at deep hypothermia, we were able to successfully protect the brain for more than 90 minutes by running antegrade brain perfusion for 5-minute periods every 30 minutes. He was extubated the day after surgery without a neurologic deficit. We therefore usually run antegrade brain perfusion, if not throughout the period of circulatory arrest for total arches, at least at intermittent intervals when convenient from the point of view of visualizing the field and suturing. The balloon occlusion catheter can easily be led out of the field so that it does not obstruct the view. Because the right subclavian artery is perfused in these patients, once the balloon catheter is withdrawn from the arch, the arch is flushed of any embolic material before anastomosis is completed. If an elephant trunk procedure is being used, a side graft to the elephant trunk is not required for antegrade perfusion, because the right subclavian artery is being perfused. Similarly, in patients undergoing acute dissection repairs, a side graft to the aortic arch is not required because the subclavian artery is being perfused.^{1,10,4,18,19}

Fourteen percent of patients have an incomplete circle of Willis; however, extracranial collaterals will still allow the perfusion of the left brain in most of these patients. Although unilateral perfusion is adequate for shorter circulatory arrest times, (<45 min), bilateral perfusion through an additional left carotid cannula would be advisable.^{1,4,10,18-20,42,54}

Future research is needed to determine the best perfusion method for brain protection during total arch replacements, including the best temperature.

OPERATIVE TECHNIQUES

The operative procedures for aortic arch replacement are most commonly hemiarch repairs or entire arch repairs, with or without a distal descending elephant trunk procedure.⁴ Other unusual types of operations are options in specific situations. To a large extent, the choice of aortic arch procedure is influenced by the proximal aortic root or by the ascending aorta operative technique, whether it is a composite graft, root remodeling, separate valve and graft, valve reimplantation, Ross procedure, or no valve procedure. Also, in choosing a valve type, it is important to consider durability, particularly for biological valves, as a third or fourth operation will be complicated.⁵³

Hemiarch Replacement

Hemiarch replacement of the aortic arch is the simplest and quickest operative technique. The anastomosis can be achieved in 5 to 15 minutes depending on the aortic arch pathology. Once the patient has been cooled down and the method of brain protection and perfusion has been decided, the patient's circulation is stopped with the patient in the head-down position. In patients undergoing reoperations, we use one of two approaches: either full median sternotomy or a minimally invasive approach. The ascending aorta is then opened between stay sutures. A decision is made as to whether the aortic arch should be transected for the anastomosis. Briefly, transection of the aorta is indicated for acute aortic dissections in those patients who have had an aortic root procedure in which the aorta has already been transected proximally, and for most patients who need hemiarch replacements. The reason is that it is easier to obtain hemostasis at the distal anastomosis if the aorta was transected, and thus the risk of false aneurysm formation is also less. The transection line usually runs from the proximal base of the innominate artery to the midpoint of the lesser curve of the aortic arch. In patients with acute dissections, it is important to be certain that all layers are transected, and that the adventitia is freed of the posterior-lying pulmonary artery and a bit further cranial to the pulmonary artery to ensure adequate tissue is present for effective suturing. The anastomosis is performed with a running 4-0 or 3-0 Prolene suture, dependent on the pathology. For patients with acute dissections, it is best to use a 4-0 or even 5-0 Prolene. When the anastomosis is near completion, the graft and arch are filled with blood by restarting the arterial flow from the pump. Any potential embolic material is sucked away, and gaseous pockets are evacuated. To further reduce risk of gaseous embolism, carbon dioxide is run into the operative field during the procedure. The anastomosis is completed and the suture is tied down. The patient is rewarmed, and the proximal ascending aorta anastomosis or aortic root procedure is completed.

In patients who have either had aortic root remodeling using techniques described by David and Feindel, Sarsam and Yacoub, or us, or who have a modified valve reimplantation procedure, an interposition graft is usually required between the aortic root graft and the aortic arch.^{37,55-57} If, however, the valve remodeling was done while cooling, an interposition graft may not be necessary. However, when the patient has undergone aortic valve replacement only, the hemiarch graft is used to suture the proximal anastomosis immediately above the aortic valve and coronary arteries. When a composite valve graft will be inserted, the proximal anastomosis of the composite valve graft to the aortic valve annulus and the left main coronary artery anastomosis can first be performed while cooling the patient, and the hemiarch anastomosis can be done directly to the composite graft without using an interposition graft, but always being careful to de-air the graft. Alternatively, if the patient cools quickly, a separate hemiarch graft is placed and later anastomosed to the proximal composite valve graft with a graft-to-graft anastomosis while the patient is rewarmed.

In patients who have had a homograft inserted with an aortic root repair, a decision needs to be made as to whether prosthetic polyester graft material should be used for the hemiarch, or whether a homograft (without an aortic valve) (see Fig. 68-7) should be used to bridge the gap between the aortic valve and the homograft. In patients with extensive infection of a previously inserted graft (e.g., a composite graft), we replace the aortic root with a new homograft and use another homograft to bridge the gap between the root homograft and the aortic arch so that there is no prosthetic material other than Prolene suture material (see Fig. 68-7B). In most cases, these grafts are wrapped with omentum to further obliterate any dead space. For those patients undergoing reoperations who have extensive scar tissue formation that restricts the ability to transect the proximal and distal aorta, the hemiarch anastomosis may be done inside the aortic arch without transecting the aorta. Rarely, if bleeding cannot be controlled, a Cabrol fistula can be formed from the aneurysm sac to the right atrium or the superior vena cava.

A variation on the hemiarch replacement is a long tongue of the graft used to replace the entire aortic arch, potentially down onto the descending aorta to approximately the middle third of the descending aorta, depending on the size of the aortic arch aneurysm (see Fig. 68-2). When using a long tongue for the total aortic arch replacement and down the descending aorta, there are some points worth noting. First, if the anastomosis is quite far down the descending aorta, parachuting the distal anastomosis makes it easier. Second, the patient should be warned before surgery that hoarseness may occur because the recurrent laryngeal nerve often cannot be preserved where it wraps around the distal aortic arch. Third, hemostasis at the distal anastomosis must be secure before continuing the operation, after doing the arch repair, because obtaining hemostasis is much more difficult once the graft is pressurized and connected proximally. Fourth, the extent distally to which the anastomosis can be performed may be judged, to some extent, by examining the CT scan or the left anterior oblique view of the arch on magnetic resonance angiography or cardiac catheterization. As a rule, an anastomosis can be easily performed no more than a few centimeters beyond the lowest level of the lesser curve of the aortic arch: the larger the aortic arch aneurysm is, the farther down the descending aorta within the descending aorta the anastomosis can be performed. If the anastomosis cannot be performed through the aortic arch, an alternative method should be considered (see Replacement of the Entire Aortic Arch, later). When doing a hemiarch with these long "tongues," care must be taken that the aortic graft not become stenosed or badly kinked. This may obstruct blood flow through the repaired aortic arch, resulting in excessive cardiac afterload. This may progress to either early acute heart failure or later ventricular hypertrophy and congestive heart failure if the gradients are too large.

Replacement of the Entire Aortic Arch

Replacement of the entire aortic arch can be done with or without a distal elephant trunk procedure. The

procedures involving an elephant trunk will be discussed first (Fig. 68-12).

Multiple variations of elephant trunk procedures have been used, including hybrid procedures. We have classified them as follows (Fig. 68-13).⁵⁸

Type I: Classic elephant trunk: ascending tube graft with total arch replacement and elephant trunk anastomosis in classic position distal to left subclavian artery (LSCA)

Type Ia: Type I repair with stent graft

Type II: Ascending aorta tube graft with arch replacement and elephant trunk anastomosis proximal to LSCA

Type IIa: Subsequent thoracic stent graft with proximal landing zone covering LSCA and a descending-to-LSCA bypass

Type III: Elephant trunk placed into large descending aortic aneurysm used as a landing zone for distal thoracic stent graft

Type IV: Ascending aorta tube graft with classic elephant trunk anastomosis into distal thoracic aneurysm with branched graft for total arch replacement

Type IVa: Ascending branched graft for replacement of ascending aorta and arch, with end-to-side elephant trunk in classic position

Type IVb: Subsequent thoracic stent graft in type IV repair

Type V: Ascending aorta tube graft with elephant trunk anastomosis proximal to brachiocephalic artery and a branched graft for total arch replacement

Type Va: Type V repair configuration with thoracic stent graft in distal aneurysm

In type I repairs, to shorten the period of circulatory arrest, the elephant trunk and inverted graft should be prepared while the patient is cooled. This is done by first suturing and tying a silk stitch to the end of the graft that will be used for the proximal repair of the ascending aorta. The distal elephant trunk should be approximately 10 to 15 cm in length. If the second stage will be done with stent grafts (type Ia) because of comorbid disease (e.g., chronic pulmonary disease), then metal clips and a loop of wire (pacing) are attached to the distal end. The proximal part with the stitch attached to it is then inverted into the distal elephant trunk. It is important to ensure that the edge of the inversion is at the same level and smooth. If retrograde brain perfusion or circulatory arrest alone is used and the subclavian artery has not been used for arterial inflow, a side graft needs to be attached to the aortic arch and inverted into the distal elephant trunk. This side graft should be attached approximately 2 to 4 cm proximal to the edge of the inverted graft. If the right subclavian artery is used for arterial inflow, there is no need to attach a side graft to the elephant trunk graft.

Once circulatory arrest is established and the patient is in a head-down position, the graft is fed into the descending aorta, ensuring it is neither kinked nor twisted into a spiral. In patients with chronic dissection, the septum or flap should be excised as much as possible so that the graft perfuses both true and false lumens.

Perfusion of either the true or false lumen alone may result in paraplegia or renal failure. It is also important that the elephant trunk not be excessively long. In a previous review of 84 elephant trunk procedures,⁹ three patients developed paralysis postoperatively, one with dense paraplegia and the other two with paraparesis from excessively long elephant trunks. Subsequent to shortening the length of the elephant trunk, this has not been a problem. The reason for this appears to be either that the elephant trunk is too long and perfusion of the intercostal arteries is inadequate, or that, as noted at the second-stage procedure, extensive clot formation occurs around the elephant trunk, which can occlude critical intercostals. Because of this clot formation, when using the elephant trunk, patients often require multiple platelet transfusions as the clot builds up around the elephant trunk in the descending aorta.

The elephant trunk graft material should be one of the collagen-coated woven grafts and not a gel-coated graft. The gel of gel-coated grafts is absorbed quickly. At the time of the second-stage operation, bleeding from a proximal elephant trunk can be excessive and potentially uncontrollable because the graft is porous after the gel has been absorbed.

The anastomosis between the inverted edge of the elephant trunk graft and the distal aortic arch beyond the left subclavian artery is then performed. The patient should be warned that hoarseness may occur postoperatively, as this procedure is in the region of the recurrent laryngeal nerve.

Reasons for inverting the graft on itself and placing it in the descending aorta are several.⁹ First, the anastomosis is easier to perform, even though it can be difficult to drive the needle through a double layer of graft material. However, with collagen-coated grafts, this is not much of a problem. Second, when the inverted graft is withdrawn from inside the elephant trunk, it has the effect of tightening the anastomosis, improving hemostasis at the distal anastomosis. Third, the larger contact surface area between the graft and aortic wall is increased so that there is less bleeding past the anastomosis. Fourth, if the graft is not inverted, suturing in a tight space between a graft and the aorta in a deep V results more often in the aorta's tearing, with the potential for a disastrous rupture in the postoperative period. This problem of rupture was experienced in the early period of using the elephant trunk technique without inverting it.⁹

One of the problems with elephant trunk procedures is the risk of rupture during the interval between the first

operation and the second-stage operation. Rupture of the descending aorta continues to be a potential risk of the elephant trunk procedure during the postoperative period, because the systemic inflammatory response results in release of collagenase and elastinase, which can result in rupture of the aneurysm. Furthermore, the aneurysm may grow in the interim, while the patient is recovering from the first operation. In Safi and colleagues' series from 2001, the interim mortality rate was 3.6%, and 75% of deaths were caused by aneurysm rupture.⁵⁹ Because of the interval aneurysm growth and risk of rupture, patients need to be closely followed. If a hybrid second-stage procedure is planned, this can be done at the time of the first stage or before hospital discharge. We reviewed our series of elephant trunk and endovascular completion and demonstrated good early and mid-term results. In the mid to late term, there is a risk of stent migration and endoleak; therefore, lifelong imaging follow-up is required. Alternatively, a stent graft can be inserted antegrade into the elephant trunk to anchor it, or the separate stent graft can be sewn into position in the distal arch; the latter approach, however, has a tendency toward higher complication risk^{58,60} (see [Frozen Elephant Trunk](#), below).

A second-stage operation is usually planned after the patient's recovery from respiratory problems related to the first operation, usually 6 weeks to 4 months after the first stage. Alternatively, if the patient is in poor condition after the first operation, including experiencing respiratory problems, we electively proceed to stent grafting the elephant trunk as part of the second-stage procedure, provided that the descending aorta down to the celiac artery can be stented. On occasion, a limited thoracoabdominal incision has been used to place bypasses from the iliac artery to the visceral vessels and, thereafter, a stent graft has been inserted to replace the remaining aorta from the elephant trunk down to the aortic bifurcation or iliac arteries. With the increasing use of thoracoabdominal stents, second-stage stenting with inclusion of the thoracoabdominal aorta is also an option. In patients with acute dissection, total arch replacement is avoided if possible. If total arch replacement must be done, an elephant trunk can be placed in the true lumen in the descending aorta after transecting the aorta beyond the left subclavian artery. Transecting the aorta ensures that all layers are cut and a completely hemostatic suture line is achieved with a rim of Teflon felt around the aorta. The recurrent nerve usually ends up being transected.

FIGURE 68-12 ■ Steps for the elephant trunk procedure technique modified by inverting the graft and placing it in the descending aorta. (1) A side graft is sewn to the graft that will be used for the aortic replacement and then the graft is inverted on itself, including the side graft. The distal extent of the elephant trunk should be 10 to 15 cm in length, and a rim of approximately 1 to 2 cm is left between the side graft and the inverted edge turned down for sewing. If the right subclavian artery is used for arterial inflow, the side graft is not necessary. (2) When the patient is cold enough, circulation is arrested and the aorta is opened. (3) The aorta can be transected to improve exposure, if needed. (4) The previously prepared graft is then placed in the descending aorta. (5) The distal anastomosis is performed starting at the three-o'clock position as the surgeon looks at the anastomosis. (6) The inner inverted tube is then pulled back into the operative field. (7) The posterior suture line is performed for the aortic arch. (8) The anterior suture line is performed. Once the anastomosis has been completed, arterial inflow is started through the side graft again to perfuse the brain if the right subclavian artery has not been used. (9) At the second stage of the operation, the graft is exposed in the aneurysm and clamped. It is not necessary to encircle the aorta to perform this, because the graft is surrounded by clot and can be exposed without much bleeding and then digitally clamped before applying a mechanical clamp. (10) The remainder of the aorta is then repaired. (11) For thoracoabdominal aneurysms, an interposition graft is necessary to complete the repair.

FIGURE 68-13 ■ Classification of anastomotic sites of elephant trunk for repair of thoracic aorta disease. Classic elephant trunk: (I) ascending tube graft with total arch replacement and elephant trunk anastomosis in classic position, distal to left subclavian artery (LSCA); (Ia) this repair with subsequent stent graft. (II) Ascending aorta tube graft with arch replacement and elephant trunk anastomosis proximal to LSCA; (IIa) subsequent thoracic stent graft with proximal landing zone covering LSCA, and a descending-to-LSCA bypass. (III) Elephant trunk placed into large descending aortic aneurysm to be used as a landing zone for distal thoracic stent graft. (IV) Ascending aorta tube graft with classic elephant trunk anastomosis into distal thoracic aneurysm, with branched graft for total arch replacement; (IVa) ascending branched graft for replacement of ascending aorta and arch, with end-to-side elephant trunk in classic position; (IVb) subsequent thoracic stent graft in type IV repair. (V) Ascending aorta tube graft with elephant trunk anastomosis proximal to brachiocephalic artery and a branched graft for total arch replacement; (Va) this repair configuration with thoracic stent graft in distal aneurysm.

Type II is the most common alternative elephant anastomosis; using this type, the anastomosis is performed between the common carotid and the left subclavian artery (Fig. 68-14).⁶¹ If the distal aortic arch beyond the left subclavian artery is enlarged and there is no “landing

site” for doing the distal anastomosis, then the aortic arch is often more narrow between the left common carotid and left subclavian artery. Thus, doing the anastomosis at this site results in a shorter circulatory arrest period, because the suture line is shorter and exposure is better.

FIGURE 68-14 ■ **A**, Diagram of a modified elephant trunk technique with an anastomosis performed between the left common carotid and left subclavian arteries. **B**, Completion of the second stage of the elephant trunk procedure, with a tube graft to the left subclavian artery.

The downside of doing the anastomosis between the left common carotid and left subclavian arteries is that the left subclavian artery needs to be anastomosed to the elephant trunk during the second-stage operation. This is typically done with an interposition graft. An alternative method is to attach the left subclavian artery to the left carotid artery at the first-stage operation. Another strategy would be to oversew the left subclavian artery and use a sidearm graft through the first or second intercostal space to revascularize the left axillary artery, as described by Baeza and Svensson.⁶²

Once the distal anastomosis has been performed, the inner inverted graft is withdrawn and an opening is made opposite the greater vessels. The posterior suture line is performed, followed by the anterior suture line. The graft is flushed, any potential embolic material is removed, and then the graft is clamped. The graft is checked for hemostasis at both the distal anastomosis and the aortic arch. The proximal anastomosis is performed to the ascending aorta, depending on the root technique used.

Increasingly, patients who are referred for descending thoracic or thoracoabdominal operations have severe

cardiac disease, either valvular or coronary.⁶³ If the proximal descending aorta or distal arch is also enlarged, we place a descending thoracic elephant graft with the proximal anastomosis sewn just beyond the left subclavian artery in preparation for the second-stage operation or stent grafting (type III). One reason for this is that the left subclavian artery can also be used. If not, the distal arch could not be clamped at the second operation with a patent left internal mammary artery.

Japanese surgeons, when doing aortic arch replacements, like to use branch grafts to the greater vessels. Branch grafts have a neo-aortic larger graft with four-sided grafts attached end to side, typically 8 or 10 mm in size, or larger. The distal anastomosis is first performed between the neo-aortic graft and the descending aorta, followed by the greater vessel anastomoses. The left subclavian artery and the left common carotid and innominate artery are anastomosed to the branch grafts sequentially. Cannulas in the transected greater vessels are used to maintain antegrade perfusion while these anastomoses are performed. The fourth side graft is used for perfusing the aortic arch and reestablishing blood flow to the greater vessels as they become attached to the branch graft. This approach is not generally favored by most surgeons in Europe and the United States, although there is some virtue to this technique in patients with extensive calcification and atheroma of the aortic arch, when suturing beyond the atheroma and calcification in the greater vessels is required. Disadvantages of this technique are a very long pump time, potential kinking of the graft or side branches, prolonged total body systemic circulatory arrest, and the longer period of nonpulsatile flow to the brain. Indeed, for aortic arch surgery, the pump time is the best predictor of mortality and risk of stroke.^{4,34} A method we have used in conjunction with subclavian arterial perfusion is to sew a bifurcated graft to the innominate artery and carotid artery first, and then to do an elephant trunk procedure and left carotid bypass (type IV). These are then connected to the neo-aortic graft. The advantage is that the brain arrest time is 5 to 15 minutes.

A technique that can be used occasionally is to place a bifurcated graft on the anterolateral aspect of the ascending aorta, suturing the other ends of the bifurcated graft to the greater vessels so that the native greater vessel stumps in the aortic arch can be oversewn. A separate graft is used to bypass the left subclavian artery, or a left carotid subclavian bypass can be done. The aortic arch and descending aorta are then addressed with an elephant trunk (type V) or are stented (type Va) as needed, either immediately through a side graft or later. If a stent graft is to be used, a large clip can be placed at the heel of the anastomosis between the graft and the aorta to guide stent placement. The stent graft is oversized by 10% to 20% and placed with a stiff guidewire placed in the left ventricle as a rail. The major advantage of this procedure is that it can often be done without circulatory arrest and sometimes off pump. Lee and coworkers compared the series of arch debranching procedures to standard elephant trunk procedures and found equivalent results with the aortic debranching group needing cardiopulmonary bypass in 68% of patients and circulatory arrest in only

27%.⁶⁴ The rates of spinal cord ischemia, stroke, and 30-day mortality were 0%, 11%, and 16%, respectively, for arch debranching and 0%, 10%, and 20%, respectively, for standard elephant trunk.

If the entire thoracic aorta or the entire aorta is going to be replaced through both a mediastinal and a left thoracoabdominal incision, the distal anastomosis in the aortic arch does not need to be done; only the anastomosis to the greater vessels is needed. This operative technique is discussed in [Chapter 69](#). Also, if the descending aorta, arch, and ascending aorta are replaced through a “clam-shell” incision, a distal arch anastomosis is not needed.

If the elephant trunk procedure is not used for the distal anastomosis, the distal anastomosis is performed in the descending aorta with a simple running suture ([Fig. 68-15](#)). Usually, the aorta is not transected because of the risk of cutting the recurrent laryngeal nerve. The transition between the aneurysm to the normal aorta usually has fairly tough tissue to suture. As mentioned, if this is

within the proximal third of the descending aorta, the anastomosis can be performed without a problem, particularly if the parachuting technique is used. If there is an aberrant right subclavian artery without a Kommerell diverticulum aneurysm, it can be included in the repair (see [Fig. 68-2](#)). An alternative is a technique in which the graft is placed in the descending aorta while the anastomosis is performed, and then the inverted graft in the descending aorta is withdrawn for the aortic arch repair.⁴

Other Techniques

In patients with saccular aneurysms with a fairly narrow neck, a patch of graft material can be sewn to the neck in the aortic arch, usually on the lesser curve. One needs to ensure that the edge of the aorta is strong and will hold sutures. This technique is also useful for saccular aneurysms of the proximal descending aorta. However, a decision has to be made as to whether a mediastinal approach or a left thoracotomy is better. When a patch technique

FIGURE 68-15 ■ For this aneurysm involving only the ascending and aortic arch and proximal descending aorta, an elephant trunk procedure was not necessary. Note the extensive clot formation in the aneurysm shown on the computed tomography scan. The arch was repaired by sewing the graft into the proximal descending aorta and then reattaching the greater vessels as a Carrel patch.

is used, because there is usually extensive atheroma, it is advisable to use the right subclavian artery for arterial inflow to ensure that any potential embolic material is not flushed back up into the brain but rather washed into the descending aorta.

Griep and the Mt. Sinai group have described a technique of suturing a large graft to the greater vessels island and then perfusing this graft from the pump while another graft is used for doing both distal and proximal anastomoses in the aorta.^{31,38,65} Finally, an anastomosis between the graft to the greater vessels and the separate aortic arch graft is performed. This technique allows a shorter circulatory arrest to the brain but requires that additional anastomoses be performed.

In patients with extensive atheroma and calcification, endarterectomy of the aortic arch also may be required. In our experience with 45 patients, the results have been surprisingly good when doing endarterectomies at the same time as aneurysm repairs of the aortic arch.²⁹ When performing endarterectomies of the aortic arch and greater vessels, a meticulous technique must be used to ensure that no embolic material gets into the ostia of the greater vessels. For this reason, we use antegrade brain perfusion and often combine this with retrograde brain perfusion to ensure maximal flushing of the greater vessels while doing these types of repairs.²⁹

Another option is using a minimal invasive approach for re-do aortic arch surgery. The advantage of using this method at reoperations is that the rest of the heart and the right atrium do not need to be dissected out. Because the patient has typically undergone a previous aortic root procedure, an elephant trunk procedure can be done distally and the proximal anastomosis performed to the ascending aorta. We have used this method now in 125 patients with a 95% survival rate and a 2.6% stroke incidence.^{47,66,67}

We do not use the new biological glues extensively for aortic arch repairs. In our experience, patients who return for reoperations who have had repairs with these glues often have tissue that is extremely thick, hard, and often calcified, making it difficult to work with. In addition, there is the risk in aortic arch surgery that some of the glue may embolize distally; this is particularly the case with the gelatin-resorcinol-formaldehyde (GRF) glues. Infection and false aneurysms also can be problems.

For patients with aneurysms or stenosis of the greater vessels, various operative techniques can be used at the time of aortic arch surgery. Most of these involve placing bypasses from the neo-aortic graft to a more distal normal segment of the greater vessel. Sometimes, if only the origin of the greater vessels of the aortic arch is involved, these procedures can be performed without placing the patient on cardiopulmonary bypass. For example, a side-biting clamp can be placed on the ascending aorta and a bifurcated graft sewn to the ascending aorta. Alternatively, the ascending aorta can be replaced by a tube graft and the bypass graft attached to it. The distal grafts can then be used to bypass the innominate, the common carotid, or the subclavian arteries. [Figure 68-16](#) shows magnetic resonance angiograms of a patient in whom this technique was used to attach the bifurcated graft to the ascending aorta using a side-biting clamp; the two distal

grafts were routed through the chest pleural spaces and through the first intercostal space to the bilateral axillary arteries, where anastomoses were performed.⁶²

Frozen Elephant Trunk

The frozen elephant trunk technique is a single-stage approach for the repair of arch and thoracic aortic disease where a stent graft is first delivered in the descending aorta either antegrade or retrograde. The distal anastomosis of the aortic arch graft is then sewn on to the distal aortic arch with the suture line incorporating the stent.^{68,69} According to European E-vita Open Registry data, the use of the frozen elephant trunk technique for chronic dissection leads to an 80% rate of complete thrombosis in the false lumen.^{70,71} In patients with acute type A dissection, the residual dissected descending aorta present in 50% of cases is prone to aneurysmal enlargement, and up to 40% of these patients require reintervention. Roselli and colleagues described a simplified frozen elephant trunk technique to potentially address this issue.⁷² A single commercially available thoracic stent graft is delivered antegrade down the descending aorta into the true lumen. The proximal end is then trimmed and sutured into the aortic arch. In this series of 17 patients, no perioperative deaths occurred and 88% of patients had a fully thrombosed false lumen at follow-up. In a large Japanese series of 156 patients, of which 100 had dissection and 56 had aneurysmal disease, the rates for mortality, stroke, and paraplegia were 3.2%, 2.6%, and 2.0%, respectively. At 12 months, the false lumen shrank in 46% of cases and was obliterated in 37% of patients. Whether this improved remodeling of the aorta leads to long-term survival advantage is yet to be demonstrated.

Occasionally, the aortic arch cannot be replaced or operated on. A valved conduit from the left ventricular apex to the descending aorta is one option of treatment in this event ([Fig. 68-17](#)).

Finally, as hybrid operating rooms are becoming increasingly common, and with increasing familiarity and comfort with percutaneous and endovascular techniques, an expanding array of complex cases can be addressed with minimally invasive approaches. We recently performed a case where the left common carotid artery and descending aorta were concomitantly stented with a transapical transcatheter aortic valve replacement.

OUTCOMES

In a historical study from 1993 and an analysis of 656 patients who underwent deep hypothermia and circulatory arrest, mostly for aortic arch replacements, the mortality rate was 10% and the stroke rate was 7%.³⁴ This large study noted that the longer the circulatory arrest was, the greater was the risk of stroke. It is of interest that some patients tolerated circulatory arrest periods of up to 120 minutes without developing frank strokes. In this series of patients, the predictors of stroke by multivariate analysis were history of cerebrovascular disease, previous aortic surgery beyond the left subclavian artery, and cardiopulmonary bypass time ($P < 0.05$).³⁴

FIGURE 68-16 ■ **A**, Magnetic resonance angiogram (MRA) shows occluded innominate and left subclavian arteries and 50% narrowing of the left common carotid artery. **B**, Postoperative MRA after off-pump insertion of a bifurcated graft from the ascending aorta to both axillary arteries with a transpleural approach. **C**, Diagram of the completed procedure.

Results with aortic arch surgery continue to improve. Safi and colleagues' series from 2001 had a 5.1% 30-day mortality for the first stage, 3.6% interval mortality, and 6.2% 30-day mortality for the second stage. In our series of 526 unselected elephant trunk procedures, the survival rate for the first operation was 92%, with no statistical significant difference between the LCCA-LSCA (left common carotid artery–left subclavian artery) group and the classic group. The overall stroke rate was 8%. The 1-, 4-, and 8-year risk of death before second-stage elephant trunk was 16%, 22%, and 27%, respectively; the larger the descending aorta is, the greater the likelihood is of a second-stage completion.

In a prospective randomized study, we reported a survival rate of 100%, and no patient suffered stroke after aortic arch repairs.²⁹ Although 91% of patients had a neurocognitive deficit when tested between 3 and 6 days after undergoing aortic arch repairs, by 2 to 3 weeks after surgery, with repeat testing using 51 neurocognitive tests, 9% had a deficit, and by 6 months, all the patients with

new neurocognitive deficits had recovered. As mentioned, 38% of patients had had a preoperative deficit. In another analysis, of 403 patients undergoing ascending and aortic arch operations using a protocol to protect the brain as much as possible from strokes and neurocognitive deficits, the survival rate was 98%, stroke rate 2%, and incidence of neurocognitive gross clinical deficits 2.5%.⁵⁴ The predictor of death by multivariate analysis was pump time; for stroke it was aorta symptom grade, peripheral vascular disease, and pump time; and for neurocognitive dysfunction, it was New York Heart Association dyspnea class, pump time, arrest time, day extubated, and antegrade perfusion. In our recent randomized clinical trial of 121 patients with aortic arch repairs, only 0.8% had clinically evident stroke, although 9% had radiologic evidence of new stroke and 14% had new onset of neurocognitive dysfunction.⁵¹ These studies emphasize the importance of awareness that patients may have suffered silent strokes and developed neurocognitive deficits before undergoing aortic arch surgery.

FIGURE 68-17 ■ This patient had undergone previous coronary artery bypass surgery, had systemic lupus and renal disease, was on high-dose steroids, and had heart failure from aortic valve stenosis. There was extensive calcification of the ascending aorta and aortic arch, including modest stenosis of the greater vessels. **A** and **B**, A valved tube graft was placed from the left ventricle apex to the descending aorta. The operation was done without cardiopulmonary bypass. **C**, Diagram of the operative procedure.

SUMMARY

In the past, aortic arch surgery was among the most formidable of cardiovascular operations. With modern techniques, surgery for the aortic arch is considerably safer, and satisfactory results can be achieved in most patients.

Thoracoabdominal Aortic Aneurysm Repair

INTRODUCTION

Aortic aneurysm is defined as a localized dilation of the aorta that is at least 50% greater than that of nondiseased adjacent aorta. In the distal aorta, namely the descending thoracic and thoracoabdominal aorta, most aneurysms form as a result of nonspecific medial degeneration, expansion related to chronic aortic dissection, or the disease processes of connective tissue disorders. Whereas aortic

aneurysms may be either fusiform (a symmetrical dilation of the aorta) or saccular (a localized outpouching of the aorta), saccular aneurysms are uncommon in the distal aorta and tend to be associated with infection. False aneurysms (also called pseudoaneurysms) may occur and are caused by a disruption of the aortic layers that then permits leaking blood to be contained by the outermost layer of the aorta and may additionally involve the periaortic tissue. Under such conditions, the aortic wall may become dilated beyond its capacity to expand and subsequently rupture.

Contemporary surgery involves a balanced approach toward maximizing the patient's long-term benefit by replacing as much diseased aorta as possible with the need to limit aortic resection to reduce ischemic and other operative risk. Our contemporary approach to open surgical repair of the descending thoracic and thoracoabdominal aorta is presented in this chapter.

Developing a Surgical Approach to Repair

The replacement of aneurysmal sections of the distal aorta built on the successful homograft-replacement repairs of aortic coarctation by Gross and others in the mid-1940s.^{1,2} In 1950, Swan used a homograft to replace an 8-cm section of the descending thoracic aorta in a teenage patient with a coarctation-related aneurysm.³ However, it remained unclear how patients with degenerative aneurysm, who were typically far older, would respond to aortic clamping, because they tended to lack the extensive collateral circulation present in patients with congenital coarctation. Soon after Swan's initial repair, Lam and Aram⁴ attempted to replace a fusiform aneurysm of the descending thoracic aorta with a homograft. Despite the use of a shunt to maintain distal perfusion and of other adjuncts in use in this era, this repair failed because the patient became septic; the authors speculated that a successful repair may necessitate full aneurysm extirpation. In 1953, DeBakey and Cooley⁵ were able to successfully "clamp and sew" a homograft replacement of a very large aneurysm of the descending thoracic aorta that impinged on the celiac axis (this would arguably be considered an extent I thoracoabdominal aortic aneurysm [TAAA] repair today). And in 1955, Etheredge and colleagues⁶ reported a successful homograft replacement of a TAAA, and they perfused the distal aorta by using a small temporary shunt. Also in 1955, Rob⁷ reported several TAAA repairs performed by using a clamp-and-sew approach.

Over the next decade, the emerging availability of Dacron grafts facilitated the use of an extra-anatomic approach in which the graft would be placed around the aneurysm—before completely resecting it—such that it could be used as a bypass shunt during repair. For TAAAs, these repairs would be done in a bottom-to-top fashion to quickly restore blood flow to the visceral organs. Notably, all early grafts had significant limitations. Early Dacron grafts were extremely porous and readily permitted blood to seep through. Early aortic repairs were associated with high rates of death, paraplegia, and kidney failure.⁸

In 1974, Crawford⁹ detailed his experience with 28 TAAA patients. His technique for TAAA repair was vastly different from the established extra-anatomic approach embraced by DeBakey and his contemporaries. By drawing on a variety of techniques devised by others,^{10,11} as well as developing new techniques to expedite repair, he achieved an impressive survival rate of 92%. Crawford used an anatomic endoaortic-graft-inclusion technique and chose to avoid full resection of the aneurysm, carefully securing the remaining aortic wall around the replacement graft to reduce bleeding; he used island

reattachment strategies to reimplant the visceral vessels and select intercostal arteries to restore perfusion to the viscera and spinal cord. Although Crawford's approach was not immediately adopted, it became the foundation for contemporary surgical approaches to TAAA repair, and his classification¹² of TAAA repairs (Fig. 69-1) remains in use.

Natural History

Whereas the aorta expands very slowly in normal circumstances, the distal aorta tends to grow at a faster rate than the proximal aorta. Documented growth rates for the distal aorta range from 0.1 to 0.3 cm per year; growth rates are further increased in larger diameter aortas (8 cm and larger) and in patients with chronic dissection.¹³⁻¹⁵ Elefteriades and his colleagues at Yale¹⁶ identified aortic diameter as a strong predictor of rupture, dissection, and mortality. A critical diameter of 7.0 cm was identified for descending thoracic aortic aneurysms (DTAAs), with a corresponding risk of rupture or dissection of 43%. Saccular aneurysms tend to grow faster and less predictably than do fusiform aneurysms. Although it typically takes years for an aneurysm to reach a diameter-based threshold for repair, many distal aortic aneurysms increase in size and eventually progress to cause serious complications. In addition, as distal aortic aneurysms form, they are commonly lined with substantial amounts of friable, atheromatous plaque and mural thrombus.

CLASSIFICATION BY EXTENT OF REPAIR

Repair of the distal aorta poses substantially different risks than proximal aortic repair. Subsequently, operative strategy and expected outcomes vary with the extent of aortic replacement; generally speaking, risk increases as longer sections of the aorta are replaced. Thus, repair of TAAAs is typically more complicated than repair of DTAAs. Understanding of the extent of aortic involvement is the key to planning an appropriate strategy for operative repair.

Distal aortic disease may be limited to short sections of the descending thoracic aorta, or it may involve long sections of the aorta and necessitate substantial exposure. Aneurysms may begin near the left subclavian artery (LSCA) and extend beyond the level of the diaphragmatic hiatus to include varying segments of the abdominal aorta. DTAAs usually begin just distal to the LSCA and extend toward (but not past) the crura of the diaphragm. Conversely, repair of TAAAs necessitates exposing the aorta above and below the diaphragm and involves incorporating the segment from which the visceral arteries arise into the repair.

The Crawford classification schema¹² conveys useful information about TAAA repair and divides these repairs into four "extents" according to the amount of aorta replaced (see Fig. 69-1). Crawford extent I repairs involve the aorta from just distal to the LSCA to the origins of the celiac axis and superior mesenteric arteries and may also involve the renal arteries; however, these repairs do not extend into the infrarenal aorta. Extent II is the most

FIGURE 69-1 ■ The Crawford classification system for describing the extent of thoracoabdominal aortic aneurysm repair. (Used with permission of Baylor College of Medicine.)

extensive repair and involves almost the entire distal aorta, from near the LSCA to the infrarenal abdominal aorta, and it often extends to the aortoiliac bifurcation; extent II repairs generally incur the greatest operative risk. Extent III repairs involve the mid-descending thoracic aorta (below the sixth rib) and a variable amount of the abdominal aorta. Extent IV repairs begin within the diaphragmatic hiatus and extend through the abdominal aorta. Although some centers use a modified Crawford classification schema that includes an extent V repair,¹⁷ we do not; extent V repairs tend to fall under the extent III category of repair, and these two types of repair typically have similar outcomes.

CAUSES AND PREDISPOSING FACTORS

Nonspecific Medial Degeneration

Although the underlying mechanisms of aortic disease remain unknown, nonspecific medial degeneration is the most common cause of thoracic aortic aneurysms and dissections. Although the fragmentation of elastic fibers and loss of smooth muscle cells are to be expected in the

aging aorta, these processes are accelerated in medial degenerative aortic disease and lead to continual weakening of the aortic wall, aneurysm or dissection formation, and eventual rupture. Although atherosclerosis is often construed as a cause of thoracic aortic aneurysms, it may be merely a concomitant condition rather than a distinct cause of aortic aneurysm.

Chronic Aortic Dissection

Chronic dissection is a common cause of TAAA; consequently, reported rates range from 15% to almost 40% of TAAA repairs.^{18,19} Aortic dissection (which is more fully covered in [Chapters 70 and 71](#)) usually begins as a tear in the innermost layer of the aortic wall. This tear allows pulsatile blood flow to cause a progressive separation of the medial layers, thereby creating two channels of blood flow within the aorta ([Fig. 69-2A](#)). This process substantially weakens the outer aortic wall, leading to aortic dilation and eventual aneurysm formation. Chronic dissection in the distal aorta occurs in survivors of acute DeBakey type I and III dissection events. Although it is generally assumed that chronically dissected aortas of either type dilate at similar rates, emerging evidence

FIGURE 69-2 ■ Computed tomography scans showing key diagnostic findings. **A**, Chronic distal aortic dissection; the dividing septum is relatively straight (arrow), and the true (T) and false (F) lumens are indicated. **B**, Mycotic aneurysm, which is sacular in shape (arrow). **C**, Infection of an endograft; gas bubbles, indicated by arrows, may be seen near the endograft. (Used with permission of Baylor College of Medicine.)

suggests there may be differing rates of expansion between types.²⁰ Moreover, for incompletely understood reasons, patients with chronic dissection may also develop a superimposed acute dissection; this is a dangerous development, and urgent treatment is warranted.

Connective Tissue and Genetic Disorders

Connective tissue and related genetic disorders occur in 4% to 14% of patients who undergo DTAA or TAAA repair.^{19,21-24} These disorders range from the relatively well-established Marfan syndrome (MFS) to lesser known, emerging disorders such as Loeys-Dietz and aneurysms-osteoarthritis syndromes. Of these conditions, MFS is the most common in DTAA and TAAA patients; however, surgeons should be aware of the other, more aggressive disorders so as to best formulate individualized strategies for treatment. Most of these syndromes are suspected on the basis of clinical features or a positive family history; as needed, confirmatory genetic tests should be conducted.

Marfan syndrome is an autosomal dominant genetic disorder that predisposes patients to aortic aneurysm and dissection. Although most patients with MFS have a family history of the disease, a substantial number of patients develop the mutation *de novo*; numerous mutations in the fibrillin-1 gene have been discovered.^{25,26} It was long thought that the presence of abnormal fibrillin in the extracellular matrix reduced the strength of the aortic wall (and thus predisposed the aorta to dilation), but emerging evidence indicates that the abnormal fibrillin alters biomolecular pathways, leading to aberrant signaling of transforming growth factor beta (TGF- β) and a related cascade of events and, ultimately, to degeneration of the aortic wall matrix.²⁵ The clinical features of MFS usually include a tall and lanky stature with long limbs, eye lens disorders, mitral valve prolapse, joint

hypermobility, high palate, and aortic aneurysms in young adults.

Most commonly, MFS affects the proximal aorta, namely the ascending aorta and aortic root. Most patients with MFS who undergo distal aortic aneurysm repair have chronic aortic dissection. Whereas most of these patients are operative survivors of acute DeBakey type I dissection, a substantial number of repairs are done in patients with initially medically managed DeBakey type III aortic dissection.²⁷

Loeys-Dietz syndrome is an aggressive aortic disease that tends to affect patients at a much younger age than does MFS.²⁸ Characterized by widespread systemic arterial tortuosity and aneurysm formation, clinical features include the presence of a bifid uvula or cleft palate and widely spaced eyes (hypertelorism). In the past, many of these patients were identified as having MFS,²⁹ and like that disorder, this condition is autosomal dominant. However, Loeys-Dietz syndrome is caused by heterozygous mutations in the genes encoding TGF- β receptors I and II.³⁰ Patients with Loeys-Dietz syndrome require exceedingly careful monitoring because they are predisposed to dissection and rupture at far smaller aortic diameters than are patients with MFS.³¹

Other disorders,³² such as Ehlers-Danlos syndrome, aneurysms-osteoarthritis syndrome, and nonsyndromic familial aortic aneurysm and dissection, are currently thought to be infrequently encountered in patients who need distal aortic repair. Ehlers-Danlos syndrome comprises a spectrum of disorders of collagen synthesis; the vascular subtype (previously referred to as “type IV”) of Ehlers-Danlos syndrome involves a defect in type III collagen synthesis that lends itself to cardiovascular manifestations, chief among which is spontaneous arterial rupture.³³ Poor aortic tissue integrity tends to complicate surgical repair.³⁴ Recently identified, aneurysms-osteoarthritis syndrome is an autosomal dominant disorder caused by a mutation in the gene

responsible for transcribing TGF- β , *SMAD3*.³⁵ Clinically, this syndrome is reminiscent of Loeys-Dietz syndrome, but, in contrast, these patients also have early-onset osteoarthritis. Of note, these patients have a high incidence of aortic dissection at moderately dilated aortic diameters (4 to 4.5 cm), well below standard thresholds of repair.³⁶ Several other heritable mutations, affecting families with variable expression, have been documented in the genes for TGF- β receptors, TGF- β 2, β -myosin, *SMAD3*, and α -smooth muscle cell actin.³⁷⁻⁴¹ Although familial aortic thoracic aneurysms most commonly affect the proximal aorta, such heritable nonsyndromic disease may present as dissection or aneurysm in the distal aorta.

Aortitis

In rare cases, systemic autoimmune disorders, such as giant cell arteritis, Takayasu arteritis, and Behçet disease, may also lead to aneurysm formation in the distal aorta. A granulomatous inflammation may occur in patients with giant cell arteritis (temporal arteritis) that involves the entire thickness of the aortic wall and thus cause intimal thickening and medial destruction. Although Takayasu arteritis generally produces severe intimal thickening that causes obstructive lesions, it can also lead to aneurysm formation. A more common presentation of aortitis occurs when patients with preexisting degenerative aortic aneurysms then develop localized transmural inflammation. Although the reasons for this inflammation remain unclear, its onset can lead to expansion and further weaken the aortic wall. In addition, fibrosis and an infiltrate of plasma cells, giant cells, and lymphocytes can develop in the affected tissue. In Behçet disease, both arteries and veins are affected, and the disease process involves lymphocytic infiltration of the medial layer, which may progress to aneurysm or pseudoaneurysm formation.

Mycotic Aneurysm

In rare cases, infection of the native aorta precipitates distal aortic aneurysm formation. Such lesions are commonly called *mycotic aneurysms*, even though the responsible pathogens are usually bacteria rather than fungi. Mycotic aneurysms may form as bacteria inoculate healthy aortic tissue, which then contributes to subsequent aneurysm formation, or they may result from the secondary infection of an existing aneurysm. In addition, mycotic aneurysms may be pseudoaneurysms, rather than true aneurysms, and can develop as a late complication of previous iatrogenic aortic injury created during invasive imaging procedures or cardiac or aortic operations (e.g., aortic cannulation sites). Establishing a diagnosis for patients with a mycotic aneurysm can be exceedingly difficult because symptoms can be vague, such as a persistent low-grade fever or unexpected weight loss, and such infection is rare.⁴² Further complicating matters, there are a variety of mechanisms by which the source bacteria may infect the aorta; these include vertebral or other abscess, general sepsis or septic emboli, empyema, infected lymph nodes,⁴³ and other factors that can be difficult to elucidate. Unlike most other distal aortic

aneurysms, which tend to be fusiform in shape, mycotic aneurysms are often saccular in shape (see Fig. 69-2B) and correspond to localized areas of tissue destruction. Common causative organisms include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Salmonella*, and *Streptococcus*.⁴⁴ and more than one pathogen may be present. Outside the United States, tuberculosis aortitis may present as saccular aneurysm of the thoracoabdominal aorta, and sometimes even as multiple saccular aneurysms.⁴⁵ Of note, saccular aneurysms can be unpredictable, are prone to rapid growth rates, and tend to rupture more readily than fusiform aneurysms caused by medial degeneration; when mycotic saccular aneurysm is suspected, urgent evaluation is warranted.⁴⁶

Repair after Previous Open Aortic Repair (Noncongenital)

Over time, late complications of previous distal aortic repair may develop (Fig. 69-3); such complications include pseudoaneurysms and aneurysms that develop around sites of aortic reattachment (e.g., buttons of tissue surrounding reattached visceral or intercostal arteries may later become aneurysmal). In addition, aortic disease may progress such that previously normal sections of the aorta adjacent to the site of a previous repair may later become aneurysmal. Late complications tend to occur more frequently in patients with MFS and other connective tissue disorders and in patients with aortic infection. Overall, distal redo operation (previous open repair of the descending thoracic, thoracoabdominal, or abdominal aorta) rates tend to range from 16% to 27% in reported series of TAAA repairs.^{18,19,47,48}

Pseudoaneurysms often represent chronic leaks that are contained by surrounding tissues. The outer wall of a pseudoaneurysm develops from organized thrombus and associated fibrosis. Pseudoaneurysms can arise from primary defects in the aortic wall (such as a leak from a fistula or contained rupture) or from degraded suture lines or graft material (anastomotic leaks were common in the era of silk suture, which readily degraded, and graft infection may also degrade the suture line), from sites of previous cannulation (leaks that occur after cardiovascular surgery), or from a wire penetrating or otherwise damaging the aorta during invasive aortic imaging and testing. Anastomotic pseudoaneurysms can also be caused by tension between the graft and native aortic tissue. With modern suture, graft material, and technique, the incidences of pseudoaneurysm and other late complications have decreased; however, should they occur, urgent evaluation is warranted because they have a tendency toward rupture.

Repair after Previous Endovascular Aortic Repair

In the contemporary era, the use of aortic stent-grafts in the distal aorta is common in patients with aneurysm and dissection (this topic is fully covered in Chapters 70 and 71). Occasionally, patients who have undergone endovascular aortic repair develop problems that necessitate open repair.⁴⁹⁻⁵⁵ Open aortic repair after endovascular aortic

FIGURE 69-3 ■ Illustration showing late complications of open aortic repair. **A**, A visceral patch aneurysm has developed in the residual native aortic tissue. **B**, A pseudoaneurysm has developed near the suture line of an intercostal artery reattachment site.

procedures may be necessary to treat continued dilation of the aorta at or near the stent-graft landing zones, infection of the endograft (see Fig. 69-2C), the development of a fistula (Fig. 69-4), stent-graft collapse or migration, or ongoing aneurysm expansion, which may result in rupture. Progressive expansion of the aneurysm may occur because of an inadequate seal between the stent-graft and aorta (type I endoleak), bleeding into the aneurysmal sac from any covered branching artery (type II endoleak), a gap between overlapping stent-grafts (type III endoleak), retrograde perfusion through the false lumen into the aneurysmal sac in patients with extensive aortic dissection, or other causes.

Coarctation in the Adult (Congenital)

Aortic coarctation may occur in patients with bicuspid aortic valve or other congenital heart disease or in patients with Turner syndrome.⁵⁶ The typical presentation of aortic coarctation involves a narrowing of a short section of the descending thoracic aorta, located just beyond the LSCA; the quality of aortic tissue in this section is generally poor because it is delicate and friable. Over the past several decades, several open approaches have been used to treat aortic coarctation in early childhood, including subclavian flap repair, patch aortoplasty, and interposition aortic grafting. In adults, open or endovascular repair may be needed to treat previously undiscovered native coarctation or late complications (aneurysm, pseudoaneurysm, or restenosis) of previously repaired coarctation,^{57,58} which tend to develop in the first or second decade after initial repair.⁵⁹ The ideal repair for discrete and previously unrepaired coarctation in adults is somewhat controversial; current guidelines indicate that either an endovascular or an open repair may be performed.⁵⁶

In rare cases, adults need primary repair for extreme forms of previously untreated coarctation, such as an interrupted or a hypoplastic aortic arch (Fig. 69-5), or a long-segment aortic coarctation (also known as middle aortic syndrome and sometimes seen with rib notching); for these patients, current guidelines recommend open repair (Class I recommendation, level of evidence B). For patients with discrete restenosis after open repair, endovascular repair is recommended unless significant aortopathy is also present (Class I recommendation, level of evidence B).⁵⁶ Today, many experienced centers achieve good results by using a variety of approaches to coarctation repair, including open, endovascular, and hybrid techniques.^{57,58,60-64}

Patients with aortic coarctation commonly have hypertension, and even with treatment, hypertension remains difficult to control. It is thought that uncontrolled hypertension plays a role in the late development of aneurysms, both in patients with previous aortic repair and in those without. In previously untreated adults, extensive collateral circulation may develop; during open repair, these branching vessels may enhance the risk of operative bleeding, and these vessels are commonly ligated when possible. Patients with long-segment coarctation may be treated with extra-anatomic bypass grafts rather than in situ graft replacement.

INDICATIONS FOR REPAIR

Descending thoracic and thoracoabdominal aortic aneurysms most commonly present in asymptomatic, older patients (60 years of age and older) and are often incidentally discovered through imaging studies ordered to evaluate other, unrelated health problems. In patients

FIGURE 69-4 ■ Illustration showing the development of an aortopulmonary fistula, a rare late complication of thoracic endovascular aortic repair. Here, the stent-graft is shown to be within the true lumen. The distal descending thoracic aorta has ruptured into the lower lobe of the left lung (arrow); the false lumen continued to be perfused from re-entry sites below the distal landing zone of this stent-graft. Blood flow from collateral vessels additionally perfused the false lumen. (From Matos JM, de la Cruz KI, Ouzounian M, et al: Endovascular repair as a bridge to surgical repair of an aortobronchial fistula complicating chronic residual aortic dissection. *Tex Heart Inst J* 41:198–202, 2014, Fig. 5. Reproduced with permission. Copyright the Texas Heart Institute.)

with known risk factors for distal aortic aneurysms (as described in the previous section), imaging studies are used to carefully monitor the aorta until diameter-based thresholds of repair are met or until symptoms develop. Therefore, the management of distal aortic disease is typically dependent on regularly repeated imaging studies and enhanced awareness of emerging symptoms through patient education and optimization efforts (at a minimum, optimization efforts include strict blood pressure control and cessation of smoking).

Diagnostic Imaging Evaluation

Although developing an appropriate distal aortic imaging strategy is somewhat dependent on local expertise and equipment availability, recently efforts have been made to standardize image acquisition and reporting by suggesting specific aortic landmarks to measure (Fig. 69-6); for the distal aorta, these include the isthmus or proximal descending thoracic aorta (2 cm distal to the LSCA), the middle of the descending aorta (between the isthmus and the diaphragm), the aorta at the diaphragm (roughly 2 cm above the celiac axis), and the aorta at the origin of the celiac axis.⁴³ Aortic imaging reports should clearly state the location of aortic abnormalities (using the previously mentioned locations whenever possible) and report the maximum external aortic diameter (reporting the internal lumen diameter may fail to account for aortic wall inflammation, intraluminal clot, or mural thrombus, or identify both channels in cases of aortic dissection). Any extension of disease into branching vessels, such as is possible with chronic distal aortic dissection and other conditions, should be documented. Evidence of rupture should be reported, as well as any identified calcification or internal filling defects that are consistent with thrombus or atheroma. Ideally, results should be compared with the most recent prior imaging study available; precise measurement is needed because the yearly rate of aortic

FIGURE 69-5 ■ Computed tomographic angiograms in a patient with bicuspid aortic valve, related proximal and distal aortopathy, and coarctation. **A**, Three-dimensional reconstruction showing coarctation of the descending thoracic aorta. **B**, Axial image showing hypoplasia and tortuosity of the aortic arch. **C**, Post-repair three-dimensional reconstruction showing surgical correction of the aortic arch, descending thoracic aorta, and the left subclavian artery. (From Preventza O, Livesay JJ, Cooley DA, et al: Coarctation-associated aneurysms: a localized disease or diffuse aortopathy. *Ann Thorac Surg* 95:1961–1967, 2013, Fig. 1. Used with permission. Copyright Society of Thoracic Surgeons.)

FIGURE 69-6 ■ Current practice guidelines⁴³ seek to standardize the reporting of aortic diameters by indicating key anatomic locations to be measured. These include (1) the sinuses of Valsalva, (2) the sinotubular junction, (3) the mid-ascending aorta, (4) the proximal aortic arch at the origins of the innominate artery, (5) the mid-aortic arch, which is between the left common carotid and left subclavian arteries, (6) the proximal descending thoracic aorta, which begins at the isthmus (approximately 2 cm distal to the origins of the left subclavian artery), (7) the mid-descending thoracic artery, (8) the aorta at the diaphragm, and (9) the abdominal aorta at the origins of the celiac axis. (Used with permission of Baylor College of Medicine.)

expansion is generally quite small, and thus, detecting a small but abnormal growth rate can be challenging.

Although a routine chest radiograph may suggest an aortic abnormality, the most useful diagnostic imaging modalities include computed tomographic (CT) and magnetic resonance imaging or angiography scans of the chest and abdomen to delineate the extent of aortic and branch-vessel involvement. Since the CT was first reported to identify aortic disease in 1976,⁶⁵ it has become widely available and is the most commonly used imaging

modality for identifying aortic aneurysms. Information about the aneurysm's location and extent, external diameter, the presence of aortic dissection, the relationship to branching vessels, and anatomic abnormalities are all readily provided by iodinated intravenous contrast-enhanced CT imaging (Fig. 69-7). Such imaging may also aid in determining the presence of aortic infection, because nearby gas bubbles can be readily identified.⁴² Benefits of CT imaging include the short time needed to acquire the imaging data, the ability to render three-dimensional imaging, and the ability to provide multiplanar evaluation, as well as locating the presence of any aortic calcification or thrombus. Disadvantages of contrast-enhanced CT scanning include repeated exposure to ionizing radiation and the possibility of contrast-induced allergy or contrast-induced acute renal dysfunction in patients. Whenever possible, surgery is performed at least 1 day after contrast administration to allow time to observe renal function and, if needed, to permit renal function to return to normal.

Although magnetic resonance angiography (MRA) is not used as commonly as CT imaging to detect aortic aneurysm, it produces comparable or better aortic images and does not expose patients to ionizing radiation. It offers excellent visualization of all facets of branching vessels and facilitates the identification of left ventricular dysfunction. Disadvantages of MRA include the generally higher expense, the extended time needed to acquire imaging data (which poses a challenge in the critically ill patient), the suboptimal identification of aortic calcification, and the generation of artifacts created by ferromagnetic materials (such as pacemakers and other implants). In addition, the contrast agent for MRA, gadolinium, is associated with nephrogenic systemic fibrosis in patients with comorbid renal dysfunction.^{66,67} In young and otherwise healthy patients, such as those with MFS, MRA may be a valuable supplement to lifelong surveillance imaging because it avoids exposure to radiation. Echocardiography and ultrasonography are not used to evaluate DTAAAs because these techniques cannot adequately visualize disease involving this segment.

Diameter-Based Thresholds for Repair

All aneurysms are repaired to prevent fatal rupture. Although replacing the aorta can be life-saving in patients with aortic disease, surgical intervention carries substantial risks for both morbidity and mortality. Because of the inherent risks associated with surgical intervention, surgery is generally indicated only when the risk of rupture or other catastrophic aortic complications exceeds it. Studies of the natural history of distal aortic aneurysms (as described in a previous section) helped to formulate diameter-based thresholds of repair in asymptomatic patients. Current practice guidelines⁴³ recommend elective open aortic repair in asymptomatic patients when the diameter of a TAAA exceeds 6.0 cm; a lower threshold is recommended if the patient has a connective tissue disorder (Class I recommendation; level of evidence C). In patients with chronic aortic dissection, elective open repair is indicated when the descending thoracic aorta exceeds 5.5 cm (Class I recommendation; level of

FIGURE 69-7 ■ Three-dimensional reconstruction (A) and axial contrast-enhanced computed tomographic image (B) of a thoracoabdominal aortic aneurysm (TAAA). Note that the aneurysm is lined with thrombus and that the right kidney is severely atrophic (arrows). (From Vaughn SB, LeMaire SA, Collard CD: Case scenario: anesthetic considerations for thoracoabdominal aortic aneurysm repair. *Anesthesiology* 115:1093–1102, 2011, Fig. 1. Used with permission.)

evidence B). Although not expressly recommended for the distal aorta, elective repair of the proximal aorta is recommended when the rate of dilation exceeds 0.5 cm per year; it is reasonable to follow this recommendation in distal aortic repairs also, because such rapid growth indicates an unstable aneurysm.

Symptoms

When specific symptoms are present, they are usually related to aneurysmal expansion and compression of surrounding structures or to malperfusion related to aortic dissection. The onset of symptoms is usually considered an indication of impending rupture or significant malperfusion and should prompt urgent evaluation. Pain, the most common symptom, may be located in the chest, back, abdomen, or left flank; it may be described as a sharp or stabbing acute pain or as refractory pain. However, pain may be chronic and the cause poorly understood in these typically older patients.

Myriad other symptoms can arise, and whenever possible, a careful medical history should be obtained from each patient. In rare cases, fistulas can develop in patients with distal aortic aneurysm, and unexplained bleeding may be present. Dysphagia can result from compression of the esophagus, whereas coughing, wheezing, or pneumonitis can result from impingement on the trachea or proximal bronchi; hemoptysis may result from erosion into these structures. Hoarseness may result from partial vocal cord paralysis if the recurrent laryngeal nerve is

compromised. Pressure from expanding aneurysms can erode spinal bodies (often resulting in pain) or the bowel wall (causing gastrointestinal bleeding). Duodenal obstruction may occur through related compression. In rare cases, jaundice can result from compression of the biliary tract. Compression of the inferior vena cava or iliac vein can result in distal venous stasis and can present as an abdominal bruit, with widened pulse pressure and edema, and may result in heart failure.

Additional symptoms related to embolization, frank rupture, or either acute-onset dissection or expanding chronic dissection can result. Plaque and thrombus may embolize distally, causing occlusion and thrombosis of the visceral, renal, or lower extremity branches and subsequent malperfusion. Shock, refractory hypertension, or rapid aortic expansion may indicate existing or pending rupture; DTAAAs tend to rupture into the pleural cavity, often resulting in severe hemorrhagic shock. Spontaneous paraplegia; abdominal pain; cold, blue, or painful extremities; nausea; vomiting; and incontinence or abnormal urination can be signs of malperfusion caused by aortic dissection.

The assessment of possibly aneurysm-related symptoms is essential to developing an appropriate management plan. Patients who develop symptoms undergo surgical repair regardless of aneurysm diameter. The most common indication for emergent repair of a TAAA is aortic rupture or an acute dissection superimposed on an existing chronic dissection; often such dissection rapidly progresses to aortic rupture. Although emergent

repair is well understood to carry greater operative risk than does elective repair, any inappropriate delay of repair risks death; appropriate delay includes transfer to an experienced center.

Contraindications to Repair

Contraindications to open repair of the distal aorta are patient-specific and individualized to the experience of each surgeon. In general, patients with limited life expectancy are not candidates for open surgical repair, although aortic repair in survivable forms of cancer may be warranted before its treatment. Although patients at prohibitive risk of open surgical repair are sometimes offered hybrid endovascular repair, such repair in patients with TAAA involves invasive debranching of the visceral arteries and is generally poorly tolerated by patients, except in a handful of centers.⁶⁸ Operative risk models for TAAA repair commonly identify advanced age as a predictor of early death⁶⁹; operative results in patients 80 years and older tend to be somewhat poor.⁷⁰ In addition, patients should be presented with information regarding the risk of developing life-altering complications such as stroke, renal failure resulting in dialysis dependence, and paraplegia. Other patient-specific comorbid risks include chronic renal insufficiency, chronic obstructive pulmonary disease, heart failure, and coronary artery disease.^{71,72}

STRATEGY FOR REPAIR

Preoperative Evaluation

Comorbidities that are typically considered predictive of operative risk should be carefully evaluated and modified whenever possible to mitigate risk; similarly, preoperative evaluation of patients' physiologic reserve is critical to obtaining a beneficial outcome. Except in those patients who require emergent repair, all patients should undergo a thorough preoperative evaluation emphasizing cardiac, pulmonary, and renal function, as well as a careful review of imaging studies. As needed, additional studies may be warranted; in patients identified as high risk for carotid artery disease, carotid Doppler ultrasonography is warranted, and potential clotting problems or cirrhosis may be evaluated with coagulation and liver function tests.

Cardiac Function

Patients need significant cardiac reserve to tolerate thoracic aortic clamping. Transthoracic echocardiography and electrocardiography are routinely used to assess cardiac function. Patients with an ejection fraction less than 30% or with symptoms of coronary artery disease should additionally undergo cardiac catheterization or, when necessary, a noninvasive assessment of myocardial perfusion (such as dobutamine echocardiography or a dipyridamole thallium scan). When significant coronary artery disease is identified in an elective surgical candidate, myocardial revascularization is recommended before aortic replacement. Patients who have already undergone coronary artery revascularization should be

FIGURE 69-8 ■ Drawing of a thoracoabdominal aortic aneurysm repair in a patient with a patent left internal thoracic artery-to-left anterior descending coronary artery graft. The proximal anastomosis is being performed while the aorta is clamped between the left common carotid and subclavian arteries. Myocardial perfusion is maintained through the carotid-subclavian bypass graft. Thus, the potential for causing cardiac ischemia during repair is mitigated. (From Jones MM, Akay M, Murariu D, et al: Safe aortic arch clamping in patients with patent internal thoracic artery grafts. *Ann Thorac Surg* 89:e31–32, 2010, Fig. 2. Used with permission. Copyright Society of Thoracic Surgeons.)

carefully assessed; if the left internal thoracic artery has been used to revascularize the heart, and if the aortic clamp may need to be placed proximal to the origin of the LSCA (a common placement site for DTAA and extent I and II TAAA repairs), a left carotid-to-subclavian artery bypass (Fig. 69-8) can be performed before aortic replacement to avoid myocardial ischemia.⁷³

Pulmonary Function

Sufficient pulmonary function is needed to tolerate the single-lung ventilation that is commonly used in distal aortic repair; pulmonary complications are the most common form of postoperative complication and typically affect 30% or more of patients with distal aortic repair. In most patients, lung function is assessed with pulmonary function studies, including forced expiratory volume in 1 second (FEV₁) and arterial blood gas analysis. All patients with an FEV₁ greater than 1.0 liters and a blood carbon dioxide partial pressure (PCO₂) less than 45 mm Hg are considered satisfactory surgical candidates. Whenever possible, in patients with an FEV₁ less than 1.0 liter or a PCO₂ of greater than 45 mm Hg, pulmonary function is optimized over a period of 1 to 3 months by means of smoking cessation, bronchodilator therapy, weight loss, an appropriate exercise regimen, and

pulmonary rehabilitation. Optimizing lung function preoperatively is thought to lessen postoperative pulmonary complications. In addition, diaphragm-sparing techniques may be selectively used in patients with particularly poor pulmonary function.

Renal Function

Preoperative renal dysfunction is an important predictor of early postoperative mortality and morbidity after aortic replacement.^{48,71} Unfortunately, CT imaging (which is often used in planning aortic repair) may adversely affect renal function through the necessary use of nephrotoxic contrast agents. In patients with borderline renal function, preventive measures are taken before imaging studies are conducted. A solution of 5% dextrose and Ringer lactate solution with 25 g/liter mannitol and 1 amp/liter sodium bicarbonate may be administered intravenously before image acquisition. In addition, acetylcysteine may be administered before and after such studies to further reduce the risk of contrast-induced nephropathy. When possible, after CT scanning or aortography, surgery is delayed for 24 hours or longer until renal function has returned to baseline.

Evaluation of Imaging Studies

Essential to forming an operative strategy, available imaging studies should be carefully reviewed and, if necessary, additional imaging studies should be obtained to clarify findings. The diameter of the aorta throughout the diseased and nonaneurysmal portions is established. Potential sites for aortic clamping and cannulation are reviewed for calcification, dissection, and mural thrombus. Close attention is paid to anatomic variants, such as a retroaortic left renal vein, as well as any previous use of the left internal thoracic artery to provide coronary revascularization. The locations of particularly large intercostal arteries are noted. Branching vessels, such as the visceral and renal arteries, are carefully assessed for stenotic origins, their spatial orientation relative to each other, and, in cases of chronic aortic dissection, whether blood is supplied by the true lumen, false lumen, or both.

Anesthesia

It is crucial to establish communication among the surgeon, anesthesiologist, and perfusionist during distal aortic repair. Adequate intraoperative monitoring and venous access must be ensured because patient hemodynamics can fluctuate greatly during aortic clamping and unclamping. Patients generally undergo placement of a right radial or brachial arterial line, a pulmonary artery catheter, and a large-bore central venous catheter that permits rapid fluid administration. Whenever blood flow through the LSCA will be compromised by the site of aortic clamping, the arterial catheter is placed in the right radial artery. To monitor temperature, a probe is placed in the patient's nasopharynx.

A method for anesthesia induction is specifically chosen according to each patient's hemodynamics, cardiac contractile function, and whether or not motor-evoked

potential monitoring of the spinal cord will be used. Muscle relaxation is typically achieved by using pancuronium bromide. Because the presence of many muscle relaxants will not allow a proper motor-evoked potential response to be generated, shorter acting muscle relaxants are used during intubation and then reversed. A double-lumen endobronchial tube or left mainstem bronchial blockade is used to orotracheally intubate all patients and permit selective deflation of the left lung; this ensures adequate exposure of the descending thoracic aorta and reduces the chance of damage to the lung from handling while the patient is heparinized. If the tracheobronchial anatomy becomes distorted from pressure exerted by a large aneurysm, a standard left-sided double-lumen tube will be difficult to use; in this case, a right-sided tube, placed with fiberoptic guidance, will usually work. In extent IV TAAA repairs, left lung isolation is not as critical to obtaining sufficient exposure.

Attention to volume status by the operative team during aortic replacement is important for avoiding wide fluctuation in blood pressure and, perhaps, distal organ ischemia. Frequent arterial blood gas analysis and close monitoring of serum electrolytes and hematocrit are necessary. To maintain filling pressures, hydration with crystalloid solutions begins at the start of the operation. Mannitol may also be administered at the induction of anesthesia to help maintain diuresis and enhance renal perfusion. Aortic cross-clamp placement causes a large increase in afterload. During aortic cross-clamping, all attempts should be made to keep systemic blood pressure within a normal range and thus avoid hypertension related to clamping. As needed, vasodilating agents such as nitroglycerin, nicardipine, and nitroprusside may be used. When left heart bypass is used as an adjunct, an effective means of blood pressure control in the vessels above the proximal clamp site is to increase flow through the left heart bypass circuit. Blood loss is carefully monitored, and lost blood is replaced. Reinfusion of shed blood recycled from a cell-saving device is useful in decreasing the amount of transfused blood and blood products. During periods when blood loss is extensive (such as when the aorta is being opened), rapid reinfusion permits the use of unwashed, filtered whole blood. Although the meticulous reinfusion of shed blood may at times avoid the need for transfusion, in many cases, fresh-frozen plasma and platelet transfusion are used to restore adequate clotting function and thus facilitate hemostasis.

As repair nears completion, the hypotension that usually occurs when the aortic clamp is removed is avoided or mitigated by discontinuing the use of vasodilating agents shortly before unclamping and also by infusing fluids to account for any volume lost during the repair. Typically, one can achieve hypervolemia with rapid fluid administration just before aortic clamp release. A sodium bicarbonate infusion may be used to treat any acidosis encountered during aortic cross-clamping. Whenever possible, at the conclusion of repair, the double-lumen tube may be exchanged with a single-lumen one; however, this is not always possible at this time because upper airway edema is common, so this exchange is often delayed for several hours.

Positioning

To facilitate adequate exposure, the patient is positioned on a beanbag in a modified right lateral decubitus position with the shoulders at 60 to 80 degrees and the hips flexed to 30 to 40 degrees from horizontal. To maintain the patient's position, the beanbag is suction-deflated and secured as the left arm is elevated and extended at an angle above the shoulders, similar to a freestyle swimming stroke position. Sterile draping should allow access to the entire left chest, abdomen, and both groins. Although removing a rib was common in past eras, we now avoid doing so whenever possible and instead use a table-mounted retractor to provide sufficient exposure during the repair. To reduce the risk of graft and surgical wound infection, we often soak the graft in an antibiotic solution before use; whenever possible, prophylactic broad-spectrum intravenous antibiotics are administered 1 hour before skin incision.

Multimodal Strategy Based on Extent of Repair

Despite the significant innovation that has taken place in the field of aortic surgery over the past 6 decades, successful repair remains challenging; this is largely because aortic clamping causes downstream ischemia, which may adversely affect multiple organs. Although the strategy of repair (Box 69-1) remains largely dictated by the extent of repair, we routinely use moderate heparinization (1 mg/kg), mild passive hypothermia (32–34°C), the aggressive reattachment of segmental arteries (especially

those between T8 and L1), sequential aortic clamping when possible, and cold crystalloid renal perfusion whenever the renal ostia are accessible.

Aortic repair has grown to encompass novel adjuncts designed to mitigate specific surgical morbidities, such as the major causes of morbidity and mortality in distal aortic repair—renal ischemia and spinal cord ischemia. The development and use of surgical adjuncts like left heart bypass, visceral perfusion, and cerebrospinal fluid drainage have significantly reduced the mortality and morbidity rates traditionally associated with extensive aortic repair.⁷⁴

Left Heart Bypass

Left heart bypass (LHB) is a well-supported strategy to provide distal aortic perfusion and reduce ischemic conditions.⁴³ We typically reserve LHB for patients undergoing extensive TAAA repairs (extent I and II TAAA repairs), as well as for select patients with poor cardiac function, in whom LHB effectively unloads the left ventricle and improves their ability to tolerate aortic clamping. As the proximal anastomosis is performed, we use a closed-circuit in-line centrifugal pump (without a warming device, oxygenator, or cardiotomy reservoir) to deliver isothermic oxygenated blood distal to the aortic segment being repaired. After heparin is administered (1 mg/kg), cannulas (24 Fr angled-tip cannulas) are placed first in the left inferior pulmonary vein to enter the left atrium and second in the distal descending thoracic aorta or the left femoral artery. Our preferred approach is cannulating the distal descending thoracic aorta a few centimeters proximal to the origin of the celiac axis, because this approach eliminates the need for, and potential risks associated with, femoral artery cannulation. After LHB is initiated (at a modest flow of 500 mL/min), a straight, padded aortic cross-clamp is applied to the aorta at the previously identified proximal site. A second clamp, generally a large Crawford clamp, is then placed across the mid-descending thoracic aorta to isolate the proximal descending segment. With a goal mean arterial pressure of 80 mm Hg, flows of LHB are generally increased to 1.5 to 2.5 liter/min. As mentioned earlier, using LHB allows rapid adjustment of the proximal arterial pressure and minimizes the need for pharmacologic intervention.

BOX 69-1 Current Multimodal Strategy for Surgical Repair of Distal Thoracic Aortic Aneurysms

ALL EXTENTS OF DISTAL AORTIC REPAIR

- Mild passive hypothermia (32–34°C, nasopharyngeal)
- Moderate heparinization (1 mg/kg)
- Aggressive reattachment of intercostal and lumbar arteries (especially between T8 and L1)
- Sequential aortic clamping (when possible)

ALL THORACOABDOMINAL AORTIC REPAIRS

- Cold renal perfusion (4°C) when renal ostia are accessible

CRAWFORD EXTENT I AND II THORACOABDOMINAL AORTIC REPAIRS AND SELECT OTHER REPAIRS

- Cerebrospinal fluid drainage
- Left heart bypass (during proximal anastomosis)
- Selective perfusion of celiac axis and superior mesenteric artery (following completion of left heart bypass)

CERTAIN EXTENSIVE OR HIGHLY COMPLEX AORTIC REPAIRS

- Hypothermic circulatory arrest
- Elephant trunk completion or reversed elephant trunk repair
- Extraction, full salvage, or partial salvage of prior endovascular repair

Visceral Protection

On completion of the proximal anastomosis, the LHB circuit is generally discontinued; however, typically, the LHB circuit is then converted such that it can be used to provide selective visceral perfusion with minimal added risk. As is the case with LHB, the direct perfusion of visceral arteries is often limited to those patients with extent I or II TAAA repairs. Within the origins of the celiac and superior mesenteric arteries, 9 Fr balloon perfusion catheters are used to perfuse these respective arteries with isothermic oxygenated blood, using a Y-branch off of the arterial return tubing of the LHB circuit. This greatly minimizes the total mesenteric and hepatic ischemic time during these complex aortic repairs. Although

evidence supporting this technique is lacking,⁴³ we believe its potential benefits, such as the reduced risk of postoperative coagulopathy and bacterial translocation from the bowels, outweigh any added risk. Additional techniques to enhance visceral perfusion include endarterectomy of the exposed origins, stenting with balloon-expandable stents, and replacing unsalvageable or widely displaced arteries with branch grafts.

Spinal Cord Protection

During distal aortic replacement, a large number of intercostal and lumbar arteries are sacrificed; this sacrifice is greatest during the most extensive repair (i.e., extent II TAAA repair). This loss of spinal-perfusing arteries (Fig. 69-9) is coupled with substantial fluctuations in blood pressure that are related to aortic clamping and

enhances the risk of spinal cord ischemic deficits, namely paraplegia or paraparesis. Thus, in patients who undergo the most extensive distal aortic replacement procedures (extent I and II TAAA repairs), we routinely use cerebrospinal fluid (CSF) drainage. We also use this adjunct in select patients undergoing less extensive repairs if they have previously had portions of their descending thoracic or abdominal aorta replaced. Current guidelines recommend the use of CSF drainage during both open and endovascular repairs in patients at high risk of developing paraplegia (Class I recommendation, level of evidence B).⁴³ Known risk factors for paraplegia include advanced age, comorbid renal dysfunction, emergency surgery, aortic rupture, acute dissection, extensive repair, and extended duration of surgery, as well as the position of the aortic cross-clamp, prior abdominal aortic surgery, and exclusion of the hypogastric artery.⁴³

FIGURE 69-9 ■ Illustration showing spinal cord blood supply. A single anterior spinal artery supplies the anterior two thirds of the spinal cord, and two posterior spinal arteries supply the posterior third of the spinal cord. The artery of Adamkiewicz is the largest radicular artery supplying the spinal cord and is considered to play an integral role in preserving spinal cord function. (From Vaughn SB, LeMaire SA, Collard CD: Case scenario: anesthetic considerations for thoracoabdominal aortic aneurysm repair. *Anesthesiology* 115:1093–1102, 2011, Fig. 5. Used with permission.)

CSF drainage enhances spinal perfusion by reducing competing CSF pressure. After induction of anesthesia, an 18-gauge intrathecal catheter is placed through the second or third lumbar space. The catheter permits passive drainage of CSF while allowing the CSF pressure to be carefully monitored during the operation and afterward. During repair, we aim to achieve a target pressure between 8 and 10 mm Hg. The CSF drain is left in place for approximately 48 hours after the aortic repair because spinal cord ischemia may occur immediately or in a delayed fashion postoperatively. Careful postoperative monitoring is necessitated and even brief periods of hypotension should be avoided. The benefits of this CSF drainage in extensive aortic repair have been confirmed in a prospective, randomized trial performed by our group.⁷⁵ Significant drawbacks associated with CSF drainage include intracranial bleeding, paraspinal hematoma, and meningitis, all of which can result in death. Less serious complications include a related headache, which is the most common complaint.⁷⁶

In addition, we routinely reattach pairs of large intercostal arteries, particularly if they exhibit minimal back-bleeding, to restore spinal cord perfusion. Although some groups routinely use motor-evoked or somatosensory-evoked potentials to monitor the spinal cord throughout the operation, we have not adopted this practice.^{77,78} Such approaches monitor spinal cord motor neuron function during aortic replacement to guide the selection of specific intercostal arteries for reattachment. These monitoring techniques also provide general indications to either increase spinal perfusion pressure or increase the rate of CSF drainage. Monitoring motor-evoked potentials requires preserving basal motor function, and thus, as mentioned previously, commonly used anesthetic agents to relax muscle function interfere with testing, so alternate strategies must be used. Additional strategies to preserve spinal cord function include direct epidural infusion of cold perfusate to induce regional spinal hypothermia or reducing spinal metabolism with the use of naloxone and other barbiturate-based agents. However, none of these strategies is as widely used or as highly recommended by current guidelines as is CSF drainage.

Renal Protection

Current guidelines for thoracic aortic repair⁴³ support both the administration of intraoperative mannitol (Class IIb recommendation, level of evidence C) and direct perfusion of the renal arteries with cold crystalloid or blood (Class IIb recommendation, level of evidence B). We liberally use both of these strategies. Our first randomized clinical trial compared cold crystalloid with isothermic blood and showed that cold renal perfusion mitigates acute renal dysfunction.⁷⁹ More recently, our second randomized clinical trial compared cold blood perfusion with cold crystalloid perfusion and found no benefit to using cold blood⁸⁰; therefore, to avoid potential disadvantages associated with using cold blood, we generally use cold crystalloid perfusion. Whenever the renal ostia are accessible, we insert 9 Fr balloon perfusion catheters and use these to deliver 200- to 400-mL boluses of cold (4°C)

lactated Ringer solution (prepared with 12.5 g/liter mannitol and 125 mg/liter methylprednisolone) every 15 to 20 minutes. Careful monitoring is needed to ensure that the patient is not overloaded with fluid or overcooled. In patients with a small arterial orifice, branch-vessel dissection, or atherosclerotic occlusive disease, it may be challenging to insert perfusion catheters into the renal arteries. A 6 Fr catheter, rather than the standard 9 Fr catheter, may be used in patients with small renal ostia. Catheters should be used with great care so as to avoid perforating or dissecting the renal arteries; similarly, overexpansion of catheter balloons can rupture these arteries. Similar to its use in visceral arteries, endarterectomy or stenting (or both) may be needed to improve renal perfusion; however, the risk of perforation or rupture is particularly high after endarterectomy. Bleeding related to right renal artery perforation is difficult to identify; the blood flows into the right retroperitoneum. Any unexplained hypovolemia after blood flow is restored to the visceral arteries should prompt a careful evaluation of the mesentery and retroperitoneal anatomy to rule out branch-vessel rupture. If small and readily accessible, the perforation may be sutured; if extensive or multiple perforations are present, a replacement branch graft may be needed.

Hypothermia

Although Kouchoukos and others^{81,82} routinely use deep hypothermic circulatory arrest (HCA) during DTA and TAAA repair, we prefer to use mild permissive hypothermia (32°C to 34°C) as our standard approach. Deep HCA (typically conducted between 15°C and 18°C) may introduce risks, namely coagulopathy, cold injury to the lung, retraction injury to a heparinized lung, adult respiratory distress syndrome, and an enhanced risk of stroke. We limit the use of deep HCA to scenarios where aortic clamping would be extremely challenging or generate added risk, such as rupture, aneurysms that are prohibitively large or extend into the distal transverse aortic arch (such as a “mega-aorta”), or prior endovascular repair that hinders clamping. Additional factors that may limit aortic clamping in select patients include severe atherosclerosis or calcification (i.e., porcelain aorta) and large thrombus.

When HCA is necessary, cardiopulmonary bypass is initiated by establishing venous drainage, using a 28 Fr to 32 Fr, long, multiholed cannula inserted into the left femoral vein and positioned in the right atrium. Correct positioning is crucial, and this is verified by transesophageal echocardiography. Vacuum-assisted venous drainage is initiated at flows of 1.8 to 2.4 liter/min/m² or 50 mL/min/kg. Although a cannula may be placed in the left atrial appendage or the pulmonary artery to prevent left ventricular distention, we prefer to use an angled cannula (20 Fr or 22 F) that is connected to a Y-branch of the venous line and placed through the inferior pulmonary vein into the left atrium.

The location of the return cannula depends on patient-specific factors. In older patients with severe atherosclerosis or thrombus, a 22 Fr angled cannula is placed in the lower descending thoracic aorta, whereas in younger

patients with minimal atherosclerosis, the arterial return cannula is a 20 Fr or 22 Fr straight cannula placed in the left femoral artery. Other return cannulation sites include the left common carotid artery or the left axillary artery. As systemic cooling is initiated, we administer methylprednisolone (5 to 10 mg/kg), sodium thiopental (10 to 15 mg/kg), lidocaine (100 mg), and a short-acting beta blocker for added protection. Circulatory arrest is initiated once the patient has been cooled to electrocerebral silence (usually at a nasopharyngeal temperature of 15°C to 18°C). The aneurysm is then opened, and the proximal anastomosis is constructed. Additional protective adjuncts are not used during repair because the profound systemic hypothermia achieved confers sufficient protection to downstream organs. On completion of the proximal anastomosis, the arterial line is connected to a side

branch of the graft; the main graft is then de-aired and clamped distal to the side branch, permitting pump flow to be restored to the upper body, and the remainder of the aortic repair is performed.

OPERATIVE TECHNIQUE

Exposure

DTAAs are repaired through a left thoracotomy made after single right-lung ventilation is initiated (Fig. 69-10). Commonly, this is done by entering through the sixth intercostal space; as needed, the fifth intercostal space may be used to enhance exposure of the distal aortic arch in case of rupture or large aneurysm involving the

FIGURE 69-10 ■ Approaches to exposure in descending thoracic and thoracoabdominal aortic repairs of different extents. The patient is positioned in a modified right lateral decubitus position that optimizes exposure of the descending thoracic and thoracoabdominal aorta while also facilitating exposure of the femoral arteries, if needed. **A**, A lateral thoracotomy is used for descending thoracic aortic repairs. **B**, For Crawford extent I, II, and III thoracoabdominal aortic repairs, a curvilinear incision is made. **C**, For Crawford extent IV thoracoabdominal aortic repairs, a more linear oblique incision suffices. (Reproduced with permission from Baylor College of Medicine.)

proximal descending thoracic aorta. For extensive repairs, such as extent I and II TAAA repairs, the incision is extended across the costal margin and into the abdomen and commonly terminates at the level of the umbilicus; if further exposure is necessary, this incision may be extended to address iliac artery disease. For the less extensive extent III repair, the seventh or eighth intercostal space is entered, and the incision is then curved into the abdomen. To prevent tissue necrosis, acute angulations near the costal margin should be avoided. For the predominantly abdominal extent IV repair, a straight oblique incision is made through the ninth or tenth interspace to better control the thoracic aorta. As noted previously, we generally do not remove a rib to increase exposure.

For TAAA repairs, we use a transperitoneal approach to perform medial visceral rotation. Equally acceptable, a retroperitoneal approach may be used, but our preference is for a transperitoneal approach because it enables direct evaluation of the bowel and spleen before and after aortic repair. Electrocautery is used to dissect along the line of Toldt, and the diaphragm is divided circumferentially so as to leave a 3- to 4-cm rim of diaphragm along the lateral and posterior chest wall. One or two retraction sutures are placed along the edge of the divided diaphragm on the cardiac side. Exposure generally continues distally into the intra-abdominal aorta and, when necessary, to the aortic bifurcation. The origin of the left renal artery is identified, and all attempts are made to keep the planned aortotomy incision posterior to the left ureter and gonadal vein.

Proximal Anastomosis

For patients undergoing DTAA (Fig. 69-11) or extent I or II TAAA repair (Fig. 69-12; see Video 69-1), the proximal clamp site is typically prepared in the most proximal aspect of the descending thoracic aorta, just distal to the origin of the LSCA. During preparation of the proximal clamp site, the ligamentum arteriosum is often divided, and the vagus and recurrent laryngeal nerves are identified and protected; not infrequently, the vagus and left recurrent laryngeal nerves are adherent to the aortic wall and are at risk of injury. Preserving the left recurrent laryngeal nerve is particularly important in patients with compromised pulmonary function. In cases of postoperative hoarseness, vocal cord paralysis should be suspected; if it is confirmed by endoscopic examination, patients should be offered restorative treatment via direct cord medialization.

If possible, the proximal clamp is placed distal to the LSCA to preserve its contribution to spinal cord flow. As needed, however, the proximal aortic clamp may be positioned between the left common carotid artery and the LSCA (a separate bulldog clamp is applied here; this alternate approach is helpful when there is a large distal arch aneurysm). In extent III TAAAs, the proximal clamp site is prepared more distally, corresponding to a lower incision made through the seventh or eighth intercostal space. For extent IV TAAA repairs, the proximal clamp is placed just superior to the diaphragm, and the proximal anastomosis is typically done end to end at the level of

the diaphragm or as a bevel that lies behind the origins of the visceral arteries.

The distal aortic clamp site is often located at the junction of the upper and middle thirds of the descending thoracic aorta and is prepared anterior to the hemiazygos and intercostal veins; a few of these veins may be clipped for safe positioning of the distal clamp. A distal clamp is rarely used during DTAA repair, permitting an open distal anastomosis to suitable aortic tissue; consequently, only the proximal clamp site is prepared.

In extensive distal aortic repair (extents I and II TAAA repairs), LHB is initiated, and the isolated aortic segment is confirmed to be unpressurized. This segment is then opened longitudinally with electrocautery, and the aneurysmal wall edges are retracted with size 0 silk sutures.

As the aorta is opened, it is cleared of any thrombus or debris. Typically, in DTAA and extent I and II TAAA repairs, all upper intercostal arteries are oversewn to prevent back-bleeding, thereby reducing blood loss and “steal” from the spinal cord.

The proximal descending thoracic aorta is then transected 2 to 3 cm from the proximal clamp to prepare a cuff of tissue. This cuff is carefully separated from the underlying esophagus so as not to injure or inadvertently incorporate the esophagus into the proximal anastomosis. Injury to the esophagus during the proximal anastomosis can have catastrophic consequences, including the development of a secondary aortoesophageal fistula.

For all extents of repair, an appropriately sized Dacron graft (commonly 20, 22, or 24 mm in diameter) is selected and is sewn end to end to the proximal aortic cuff with continuous 3-0 polypropylene sutures (finer suture, such as 4-0 polypropylene suture, may be needed in patients with connective tissue disorders or other conditions that make the aortic tissue fragile). Because meticulous suturing is needed to achieve hemostasis, the primary suture line is often reinforced circumferentially with either a second layer of continuous suture or with a series of interrupted pledgeted horizontal mattress sutures. If the proximal aortic clamp has been placed between the LSCA and the left common carotid artery, whenever possible, it is now repositioned onto the graft to allow perfusion of the LSCA, which provides collateral circulation to the spinal cord.

In extensive TAAA repair, after the proximal anastomosis is complete, LHB is slowly discontinued; typically, this circuit is now converted to provide isothermic visceral perfusion to the celiac axis and superior mesenteric artery. The distal aortic clamp is removed, and electrocautery is used to open the thoracoabdominal aorta down to the aortic bifurcation. As the distal aortic segment is prepared, any large pieces of thrombus are removed. In patients with chronic aortic dissection, the septum is excised (this is discussed in greater detail later). As the renal ostia become accessible, cold crystalloid is used to perfuse the left and right renal arteries.

Reattachment Strategies and Other Considerations

As mentioned earlier, we aggressively reattach one or more pairs of intercostal or lumbar arteries (segmental

FIGURE 69-11 ■ Illustrations of the clamp-and-sew technique for repair of a descending thoracic aortic aneurysm. **A**, The operation is performed through a thoracotomy (*inset*). Clamps are placed on the aortic arch between the left common carotid and left subclavian arteries and directly on the left subclavian artery. The aorta is opened longitudinally and divided circumferentially a few centimeters beyond the proximal clamp. **B**, After the proximal anastomosis is complete, the aortic clamp is repositioned onto the graft, blood flow is restored to the left subclavian artery, and the remainder of the aneurysm is open longitudinally. An open distal anastomosis completes the repair. **C**, As an alternative to the clamp-and-sew technique, left heart bypass can be used to provide distal aortic perfusion during the repair. (From Coselli JS, LeMaire SA: Descending and thoracoabdominal aortic aneurysms. In Cohn LH, editor: *Cardiac surgery in the adult*, ed 3, New York, 2007, McGraw-Hill, pp 1277–1298, Fig. 54-8. Reproduced with permission.)

arteries) as aortic repair progresses distally; such arteries that are not incorporated into the repair are carefully oversewn to prevent ongoing back-bleeding, which may contribute to spinal cord ischemia. Patent segmental arteries, particularly those between T8 and L1, are carefully inspected. We tend to select segmental arteries that are large and do not exhibit significant back-bleeding, provided that nearby aortic tissue is of suitable quality for anastomosis. Commonly, segmental arteries are reimplanted as a patch by making a small opening in the graft and constructing a side-to-side anastomosis with continuous 3-0 or 4-0 polypropylene suture. Alternatively, a small-diameter interposition graft may be used to incorporate segmental arteries into the repair by end-to-side reattachment. Whenever possible, the proximal aortic clamp is then moved immediately distal to the intercostal

patch (see Fig. 69-12F) to reperfuse that portion of the spinal cord.

The visceral arteries are incorporated into thoracoabdominal aortic repair in accordance with the extent of repair and taking into account factors such as the age of the patient, the presence or likelihood of connective tissue disease, and whether the origins of the arteries are widely displaced from one another. In addition, any stenosis or other disease involving the visceral arteries may necessitate endarterectomy or stenting to improve circulation before incorporation into the overall aortic repair. In extent I TAAA repairs, the visceral arteries are usually incorporated by surrounding them with a beveled distal anastomosis. Similarly, a beveled approach may be used in the proximal anastomosis of select extent IV TAAA repairs. In older patients with degenerative aortic disease

FIGURE 69-12 ■ Illustration of an extent II thoracoabdominal aortic aneurysm repair using a multibranched graft. **A**, A typical patient undergoing such a repair will have an aneurysm extending from the left subclavian artery down to the aortic bifurcation. In this patient, the visceral arteries are widely displaced from each other, making the traditional reattachment approach using a visceral patch difficult. **B**, The chest is entered through the sixth intercostal space. Left medial visceral rotation and circumferential division of the diaphragm enable exposure of the entire thoracoabdominal aorta. The use of table-mounted self-retaining retractors maintains stable exposure throughout the procedure. **C**, Left heart bypass (LHB) is initiated by placing a cannula in the left atrium via a left inferior pulmonary venotomy and then connecting it to the drainage line of the LHB circuit. After LHB flow is initiated, the proximal aortic clamp is placed just distal to the left subclavian artery, and the distal aortic clamp is applied across the mid-descending thoracic aorta. The aortic segment between the two clamps is opened longitudinally by using electrocautery. **D**, After back-bleeding intercostal arteries are ligated, the aorta is transected 2 to 3 cm distal to the aortic clamp and separated from the underlying esophagus. A four-branched aortic graft is tailored by stretching the graft so that it is taut, lining up the origin of the celiac graft with the origin of the left renal artery, and cutting the proximal end of the aortic graft at the point where it reaches the proximal anastomosis site (inset).

Continued

FIGURE 69-12, cont'd ■ E, After the proximal anastomosis is completed, LHB is stopped. The aorta is opened longitudinally down to the aortic bifurcation. The celiac and superior mesenteric arteries are cannulated with the balloon perfusion catheters, and selective perfusion is initiated. The renal arteries are similarly cannulated with balloon perfusion catheters to enable intermittent perfusion with cold crystalloid solution. **F,** The aortic cross-clamp is moved down to the aortic graft distal to the intercostal patch. After the graft is trimmed, the distal anastomosis is performed. **G,** The right renal artery is anastomosed. **H,** The completed repair is shown. who are free of connective tissue disorders and whose four vessels are in close proximity to one another, the origins of all four arteries may be reattached in one patch to an oval opening in the graft; in such patients, this is the simplest and most expeditious method of reattachment, and there is only a small chance a patch aneurysm will develop in the near future. Typically, in this approach, the anastomosis is made immediately adjacent to the edges of the ostia of the vessels to reduce the amount of native aortic tissue that is incorporated into the repair.

However, for various reasons, some patients need an alternate strategy for reattachment. For example, patients with connective tissue disorders are at high risk for the late development of patch aneurysms if the inherently compromised residual aortic tissue is not minimized through use of an alternate reattachment strategy. In these patients, as well as in those in whom the visceral vessels are otherwise diseased or anatomically displaced, one or more of the visceral arteries can be individually attached with either separate buttons or small-diameter Dacron grafts sewn to the aortic graft, or with a prefabricated, multi-branched aortic graft (with four pre-sewn branches). Commonly, when the left renal artery is widely displaced from the other visceral branches because of chronic dissection or extensive aneurysm expansion, it is separately reattached on a button of tissue or with a separate branch graft. In addition, in a younger patient with connective tissue disease, we generally use a multibranched graft to reimplant each vessel separately to effectively minimize native aortic tissue. An advantage of using a multibranched graft is that it permits the distal aortic anastomosis to be performed before the visceral branches are reattached; this restores blood flow to the iliac arteries and provides a needed source of collateral perfusion to the at-risk spinal cord. Although the order of reattachment depends on patient-specific anatomy and baseline renal function, the general order is right renal artery, superior mesenteric artery, celiac axis, and left renal artery.

Chronic aortic dissection is relatively common in patients undergoing TAAA repair. Although the operative approach used in these patients is similar to the one used in patients without chronic dissection, there are some key differences to consider. The dissecting membrane within the aorta is excised to locate all important branch vessels and to clearly identify the true and false lumens. If the dissection extends beyond the ostia of the visceral arteries, there are a couple of options. The false lumen can be obliterated with suture or small-diameter intraluminal stents, or the membrane can be fenestrated. Also, because of asymmetrical expansion, the left renal artery commonly becomes widely displaced; a separate opening in the graft can be used to reattach it as a small button, or it can be replaced with a separate branch graft. Care should be taken when constructing the proximal and distal anastomoses to remove a wedge of the dissecting membrane to facilitate perfusion of both true and false lumens.

Distal Anastomosis

Selecting the location of the distal anastomosis depends on the extent of repair and the degree of dilation of the distal aorta, iliac, and femoral vessels. In patients with

chronic dissection, repair is typically limited to those sections with substantial dilation, leaving the residually dissected aortic tissue in place, in the hope of increasing early survival. In DTAA repairs, the graft is typically anastomosed with continuous suture to the distal descending thoracic aorta in an open fashion. In extent I TAAA repairs, the visceral arteries are incorporated into a beveled distal anastomosis. In preparation for the distal anastomosis in extent II-IV repairs, the aortic clamp is moved distal to the site of visceral artery reattachment; this permits visceral-organ reperfusion. The distal anastomosis is then carried out in an open fashion without a clamp (an open-distal technique). If the aorta is of sufficient quality (and without substantial dilation) proximal to the iliac bifurcation, an end-to-end anastomosis is made at this level with continuous suture.

If disease continues beyond the bifurcation, we secure an additional, prefabricated bifurcated abdominal graft to the replacement graft in an end-to-end fashion by using continuous 2-0 or 3-0 polypropylene suture. The limbs of this graft are then anastomosed to the common iliac, external iliac, or common femoral arteries; flow into the internal iliac arteries is preserved whenever possible. As a general guideline, we limit replacement and target a proximal location on each bifurcation that has distal arteries of sufficient quality and caliber. If acute dissection extends beyond the location of the distal anastomosis, the false lumen is obliterated by inclusion within the suture line, effectively directing the blood flow entirely to the true lumen; as mentioned previously, chronic dissections are fenestrated to avoid malperfusion. In addition, as discussed earlier, the use of a four-branched TAAA graft permits the distal aortic anastomosis to be performed before the visceral arteries are reattached, thus facilitating perfusion of the spinal cord.

Elephant Trunk Approaches

Open repairs of extensive aortic aneurysm (i.e., repairs that involve replacing the aorta almost entirely, which are often called “mega-aorta” repairs) require a specialized approach to enable sufficient exposure. Although such repair is performed in a single stage in some centers,⁸³ in our practice these repairs are usually done in two stages and generally with an elephant trunk approach. Traditional elephant trunk repair, as introduced by Borst⁸⁴ and modified by Svensson⁸⁵ and others,⁸⁶ involves a staged approach in which the proximal aorta is replaced during the first operation and the distal aorta is replaced during the second operation (Fig. 69-13). However, if the distal aorta is at risk of rupture, or if the patient has related symptoms, the distal aorta is replaced in the first operation and the proximal aorta is replaced at a later time. This approach is called the reversed elephant trunk (Fig. 69-14), and we first used this approach almost 2 decades ago.⁸⁷

Traditional elephant trunk repairs involve first replacing the ascending aorta and aortic arch (using a standard island or contemporary Y-graft approach) and incorporating a segment of Dacron graft into the distal anastomosis such that it hangs into the proximal descending thoracic aorta. In the recent past, this was commonly done by using an island patch approach to arch replacement and

FIGURE 69-13 ■ Illustration of the elephant trunk approach to repair for (A) extensive aortic aneurysms that involve the ascending aorta, the aortic arch, and the thoracoabdominal aorta. B, During the first-stage procedure, the large aneurysm of the ascending aorta and aortic arch is replaced with a graft, a segment of which (the elephant trunk) is left suspended inside the aneurysmal descending thoracic aortic segment. C, This trunk is retrieved during the second-stage procedure and (D) used to create the proximal anastomosis. E, The completed repair is shown. (Reproduced with permission from Baylor College of Medicine.)

incorporating the trunk (usually ≈ 10 cm of extra graft material) into the distal anastomosis, which was typically located just beyond the anatomic origins of the LSCA. Contemporary approaches include the use of Y-graft arch debranching techniques⁸⁸ with a prefabricated, collared elephant trunk graft; this approach permits the distal anastomosis to be brought proximally—generally in line with the anatomic origins of the innominate artery—and the collar reduces anastomotic tension because the diameter of residual aorta can be matched by trimming the collar. Both of these approaches may be encountered in

second-stage repair, and the use of relatively short “trunks” is generally supported in the United States. In Japan, longer elephant trunks have been used, but this appears to increase the risk of paraplegia.⁸⁹

Elephant trunk repairs may be done on a prophylactic basis (such as in the case of patients with distal aortic dilation that does not yet meet a diameter-based threshold for repair) or as part of a planned extensive repair in which the second stage is usually performed within several weeks. During the second-stage completion repair, the elephant trunk greatly facilitates the proximal

FIGURE 69-14 ■ Illustration of the reversed elephant trunk approach to repair for (A) extensive aortic aneurysms that involve the ascending aorta, the aortic arch, and the thoracoabdominal aorta. In this repair, the distal aorta is of greatest concern, so it is repaired first. B, During the first-stage procedure, the thoracoabdominal aorta is replaced with a graft whose proximal portion is invaginated. The folded edge is used to create the proximal anastomosis. C, After intercostal arteries are reattached, a beveled distal anastomosis is created behind the visceral ostia.

Continued

FIGURE 69-14, cont'd ■ **D**, At the end of the first-stage procedure, the graft trunk remains suspended inside the descending thoracic aortic graft. **E**, The graft trunk is retrieved through the open aortic arch during the second stage and **(F)** is used to replace the ascending aorta and aortic arch. **G**, The repair is complete. (From Coselli JS, LeMaire SA, Carter SA, et al: The reversed elephant trunk technique used for treatment of complex aneurysms of the entire thoracic aorta. *Ann Thorac Surg* 80:2166–2172, 2005, Figs. 1-6 and 8. Reproduced with permission. Copyright Society of Thoracic Surgeons.)

anastomosis because it allows direct and secure clamping of the elephant trunk, rather than clamping the replaced arch or proximal descending thoracic aorta, which are often surrounded by dense scar tissue after the initial operation. This is especially helpful when there is a very large aneurysm involving the proximal descending thoracic segment. In patients with DTAA, elephant trunk completion repairs may be done endovascularly rather than by an open approach through a thoracotomy^{90,91}; however, this approach necessitates the availability of at least 2 cm of aortic tissue above the celiac axis to use as the distal landing zone for the endograft. Radiographic clips are usually placed on the end of the elephant trunk graft, and these can be used to guide deployment.

In a reversed elephant trunk procedure, the distal aorta is generally determined to be at greater risk of rupture than is the proximal aorta. At the initiation of repair, the graft is invaginated into itself and the proximal anastomosis is constructed between the aorta and the folded edge of the graft. During the second-stage repair of the proximal aorta, the invaginated segment of graft is retrieved and used to replace the aortic arch and ascending aorta. This approach obviates the need to perform a distal anastomosis at the aortic arch.^{87,92}

Open Repair after Endovascular Aortic Repair

In several ways, open distal aortic repair after endovascular aortic repair (Fig. 69-15) is similar to the methods

described previously, with the extent of repair dictating our standard use of surgical adjuncts. The presence of a stent-graft may limit the surgeon's ability to safely clamp the proximal aorta; when the stent-graft covers a substantial portion of the aortic arch, HCA may be necessary. In patients who present with repair failure after a previous endovascular procedure, a high degree of suspicion regarding endograft infection should be maintained, even in asymptomatic patients; the presence of infection may warrant the use of additional techniques, such as omental wrapping, placing antibiotic-irrigation catheters, and soaking the graft in antibiotics. Occasionally, an extra-anatomic approach may be justified in an infected field. When open repair is performed after previous abdominal aortic endovascular repair, an oblique incision, such as that used for extent IV TAAA repairs, is often used to ensure sufficient exposure of the visceral vessels.

Depending on circumstances, stent-grafts may be fully or partly salvaged (Fig. 69-16) in patients without infection and should be completely removed in patients with infection. The entire stent-graft can be left in place when the new aneurysm results from a progression of adjacent aortic disease rather than a late endovascular failure. Partial salvage may involve leaving a very small portion of the stent-graft proximally if it has been previously sutured directly to the aortic wall (rather than risking further damage by removing it), as is commonly done in the frozen elephant trunk approach, or more commonly, leaving relatively large portions of bifurcated abdominal stent-grafts in place after the main body of the stent-graft

FIGURE 69-15 ■ Preoperative drawing and computed tomography images illustrating (A) a thoracoabdominal aortic aneurysm caused by chronic dissection in a patient who previously underwent replacement of the aortic root, ascending aorta, and aortic arch, followed by endovascular repair of the descending thoracic aorta using the elephant trunk graft as the proximal landing zone. B, Repair involved complete removal of the stent-graft and extent II graft replacement of the thoracoabdominal aorta. (Used with permission of Baylor College of Medicine.)

FIGURE 69-16 ■ Preoperative drawing and computed tomography images illustrating (A) a thoracoabdominal aortic aneurysm caused by chronic dissection in a patient who previously underwent open graft replacement of the proximal descending thoracic aorta and endovascular repair of the distal descending thoracic aorta. Over time, the aortic disease progressed to include additional segments of the distal aorta. **B**, Repair involved partial removal of the stent-graft and extent III graft replacement of the thoracoabdominal aorta. A portion of the stent-graft was well-adhered to the aortic tissue, which permitted partial salvage of the device. (Used with permission of Baylor College of Medicine.)

is trimmed, particularly if the extension limbs are well adhered. These anastomoses are typically performed end to end and incorporate the endovascular device, the residual aortic wall, and the replacement polyester graft. Ideally, a full thickness of the aortic wall, surrounding and adherent to the stent-graft, is incorporated in the anastomosis to prevent excessive bleeding from needle holes in the endograft material. In cases of infection, a careful inspection of adjacent tissues is warranted, because there is a possibility of concomitant fistulae. An in situ swab or other measures should be used to identify the infecting agent so that an appropriate antibiotic regimen can be implemented.

Closure

On aortic unclamping and repair completion, systemic heparinization is reversed with intravenous protamine sulfate, and the adequacy of renal perfusion is assessed by administering indigo carmine dye. It is crucial to obtain secure hemostasis, so each anastomosis and cannulation site is carefully inspected for bleeding. As needed, anastomoses may be additionally secured by using reinforcing sutures with felt strips or pledgets and by prudent use of surgical adhesives.⁹³

To gently rewarm the patient and to further assess hemostasis, the field is irrigated with warm water; if necessary, additional blood products are administered.

Sufficient perfusion to the visceral organs, as well as the iliac and femoral arteries, is confirmed. The appearance of the bowel is noted, and the spleen is assessed to ensure that there are no subcapsular hematomas or capsular tears. The residual aneurysmal wall is then wrapped around the aortic graft and secured with continuous suture.

Thoracic drainage tubes are placed within the pleural cavity (anteroapical and posterobasal), and a closed-suction abdominal drain is placed in the retroperitoneum. The diaphragm is reapproximated with a continuous #1 polypropylene suture, and the intercostal space is closed with heavy braided suture and stainless steel wire. Pericostal catheters are placed to allow delivery of local anesthetic postoperatively, and the abdominal fascia, serratus anterior, and latissimus dorsi are then closed with continuous suture.

POSTOPERATIVE MANAGEMENT

Immediate Postoperative Management

A systematic approach to postoperative care is extremely important because operative complications are not uncommon and early correction is the key to minimizing the impact of emerging complications. Laboratory results are carefully reviewed, drains and fluid outputs are carefully assessed, and peripheral pulses are monitored closely.

Ideally, the patient is weaned from the ventilator and extubated within the first 24 to 36 hours after the operation; physical therapy and ambulation are emphasized early in the recovery process.

In the early postoperative period, aortic anastomoses are extremely fragile. Thus, for the first 24 to 48 hours, blood pressure is meticulously kept within a narrow range—mean pressures are maintained between 80 and 90 mm Hg. Typically, this is achieved with nicardipine and intravenous beta antagonists. For patients with particularly fragile aortic tissue, such as patients with connective tissue disorders or acute dissection, the target range for mean pressure may be reduced to 70 to 80 mm Hg. Hypotension is avoided because it can lead to ischemic complications such as delayed paraplegia or paraparesis. Even brief hypertension can disrupt suture lines, leading to severe bleeding and hypotension, or to pseudoaneurysm formation.⁹⁴

When a CSF drain is in place, intrathecal pressure is kept between 10 and 12 mm Hg during the early postoperative period. As necessary, CSF is passively drained. As soon as the patient awakens from anesthesia and before further sedatives are administered, lower extremity movement is assessed; once satisfactory motor function of the legs is confirmed, the CSF pressure target may be increased to 12 to 15 mm Hg. Patients are carefully monitored because delayed paraplegia or paraparesis accounts for roughly half of all spinal cord complications. Often, the CSF drain is stopped for several hours, and if the patient remains neurologically intact, the CSF drain is then removed; this usually takes place within 48 hours. If paraplegia or paraparesis does arise, it is treated aggressively because it can often be fully or partially reversed. If a CSF drain is not in place, one is inserted immediately; the intrathecal pressure is then reduced to less than 10 mm Hg. Additional rescue measures that may be used in conjunction with CSF drainage include optimizing hemodynamics, raising the mean arterial blood pressure to a higher range (85 to 95 mm Hg), administering steroids and osmotic diuretics, correcting anemia, and reducing fever, if present.

As emerging complications arise, corrective measures are immediately taken. Pulmonary complications are relatively common, and affected patients may need to resume ventilator support. Creatinine levels are carefully monitored, and if a significant increase occurs, we increase the patient's blood pressure by adjusting medications to better perfuse the kidneys.

It is crucial to prevent graft infection after aortic replacement, given the associated increased risk of mortality. During surgery, close attention is paid to technique and sterility, and topical antibiotics may be used prophylactically to prepare the graft. Broad-spectrum antibiotics are administered during the early postoperative course until all drains and central venous catheters are removed. After 24 hours, the retroperitoneal closed suction drain may be removed; typically within 72 hours, thoracic drainage tubes are removed provided that drainage is less than 300 mL/day.

In cases of postoperative hoarseness, vocal cord paralysis should be suspected. If it is confirmed by endoscopic

examination, patients should be offered restorative treatment with direct cord medialization.

Long-Term Management

Long-term patient education and surveillance protocols are initiated when patients prepare for discharge. Patients should be made aware that they should seek urgent treatment if concerning symptoms develop (such as the sudden onset of pain or any ischemic complications). In addition, patients should be counseled that they remain at risk for subsequent aneurysm formation in any remaining native aortic segments, including reattachment sites, even if they have no connective tissue disorders or other major risk factors for aneurysm development. Furthermore, many of our patients tend to have poorly controlled hypertension, which can contribute to the gradual weakening of suture lines and lead to the development of pseudoaneurysms. In rare cases, aortic replacement grafts become infected, which can also lead to suture-line disruption and pseudoaneurysm formation. We recommend that all patients undergo at least yearly CT imaging of the chest and abdomen. In younger patients, it is reasonable to use magnetic resonance imaging to reduce lifetime radiation exposure. Adequate surveillance imaging is especially important in patients with connective tissue disorders, especially the aggressive forms such as Loeys-Dietz syndrome.

Additional education regarding lifestyle modifications may be warranted. Maintaining a healthy blood pressure, heart rate, and weight is ideal. Patients should be educated regarding the association between smoking and aneurysmal disease. Patients in whom cocaine or methamphetamine use has precipitated dissection are counseled about the importance of cessation of drug abuse. Whereas light aerobic exercise is generally beneficial to overall health, extreme isometric exercise such as weightlifting should be limited. Similarly, although many patients can expect a full return to employment, strenuous manual labor should be avoided.

OUTCOMES

Although it is difficult to predict with certainty the consequences of distal aortic repair for individual patients, distal aortic repair poses the risk of operative death and of life-altering complications such as paraplegia, renal failure necessitating lifelong dialysis, and stroke. In general, advanced age (65 years and older), urgent or emergent repair, rupture, and extensive repair are the most valuable predictors of early death and adverse outcomes.^{69,71} Other patient-specific factors that increase operative risk include a history of stroke and poor cardiac, renal, or pulmonary function.^{48,71} Whenever possible, elective repair is planned to follow any interventions needed to improve health; in patients with known aortic disease (even those with prior repair), adherence to an imaging-surveillance protocol is crucial to avoiding emergent repair, which more than quadruples the risk of early death and substantially increases the risk of other major complications.^{48,71,95}

Without doubt, pulmonary complications are the most common type of complication to arise after distal aortic repair, affecting approximately 30% to 40% of patients.^{19,96} Pulmonary complications are highly varied and are, in many ways, largely unavoidable, because single-lung ventilation is typically necessary to provide sufficient surgical exposure. Although the lack of standardization in defining complications makes it difficult to compare complication rates over time, it is generally understood that the outcomes of distal aortic repair are better now than they were in decades past. For example, the risk of developing permanent postoperative paraplegia is now almost half of what it was in the Crawford era,^{19,48} and there is much greater awareness of the risk factors related to its development, including delayed-onset paraplegia.⁹⁴ In contrast, the risk of developing renal failure necessitating dialysis is only slightly lower now than it was in the Crawford era.^{19,48}

Descending Thoracic Aortic Aneurysm Repair

Today, the widespread use of endovascular approaches to aortic repair has reduced the use of open surgical approaches to DTAA repair. In fact, this shift has resulted in a tendency to reserve open surgery for the more complex DTAA repairs (such as those performed in patients with a failed prior endovascular repair or a connective tissue disorder). Contemporary results of open repairs of DTAA indicate that early mortality rates range from 3% to 6%, renal failure rates range from 1% to 8%, and paraplegia rates range from 1% to 5%.^{21,24,97-99} Stroke is relatively uncommon after open DTAA repair but may be more likely when HCA is used (2% vs. 3% to 7%, respectively).^{21,24,97} Regarding open coarctation-related DTAA repair, experienced centers report excellent outcomes, and results show up to 1% for early mortality and 1% to 3% for renal failure; no paraplegia has been reported.^{58,60,61}

Thoracoabdominal Aortic Aneurysm Repair

Volume-based analysis suggests that open TAAA repair is most successful when performed in high-volume centers, whereas operative mortality tends to be excessive when this procedure is performed in low-volume centers.¹⁰⁰ In experienced centers, contemporary outcomes for open TAAA repairs range from 4% to 10% for early mortality, from 4% to 6% for renal failure, and from 2% to 8% for paraplegia.^{19,81,101,102} As with open DTAA repair, stroke rates associated with TAAA tend to be relatively low. A recent analysis of National Surgical Quality Improvement Program data found a stroke rate of 2.2%.⁹⁶ Not unexpectedly, results vary greatly by the extent of TAAA repair; early mortality ranges from 5% to 8% for extent I repair, from 8% to 9% for extent II, from 7% to 13% for extent III, and from 3% to 6% for extent IV.^{18,19,22,103} Extent II TAAA repairs have been traditionally associated with the highest rates of mortality and morbidity.⁹⁵ For patients who undergo complex thoracoabdominal aortic repairs, such as reversed elephant trunk procedures or elephant trunk completion procedures, early mortality rates range

TABLE 69-1 Results of 840 Contemporary (2006-2013) Open Distal Aortic Repairs

Extent of Repair	N	30-Day Deaths	Permanent Paraplegia	Permanent Renal Failure
DTAA	84	3 (4%)	1 (1%)	3 (4%)
Extent I TAAA	192	6 (3%)	2 (1%)	7 (4%)
Extent II TAAA	239	16 (7%)	14 (6%)	23 (10%)
Extent III TAAA	148	7 (5%)	12 (8%)	14 (9%)
Extent IV TAAA	177	7 (4%)	4 (2%)	8 (5%)
Total	840	39 (4.6%)	33 (3.9%)	55 (6.5%)

DTAA, Descending thoracic aortic aneurysm;
TAAA, thoracoabdominal aortic aneurysm.

from 9% to 16%.^{92,104-106} Several centers have reported their experience with open thoracoabdominal aortic repair after endovascular repair. In many reports, these patients' outcomes are not substantially different from those of patients without prior endovascular repair unless infection is present, in which case patients with prior endovascular repair do poorly.^{52,54,55} Notably, patients with connective tissue disorders, as well as those with chronic aortic dissection, tend to have better outcomes after distal aortic repair than do other patients, probably because of their younger age, better health, and lower atherosclerotic burden.^{107,108}

Previously, we published the results of large series of DTAA and TAAA repairs that were performed over a span of 2 decades.^{24,109} In Table 69-1, we present our experience with 840 patients who underwent various extents of DTAA ($n = 84$) and TAAA repair ($n = 756$) over a recent 7-year interval. Overall, the 30-day mortality rate was 4.6%, and operative mortality (as defined by Overman et al¹¹⁰) was 7.3%. By extent of repair, 30-day mortality varied from 3% in extent I TAAA repair patients to 7% in extent II TAAA repair patients. Our overall rate of permanent paraplegia was 3.9% and ranged by extent of repair from 1% in DTAA and extent I TAAA repairs to 8% in extent III TAAA repairs. Renal failure necessitating hemodialysis at discharge remains a significant complication, with an overall rate of 6.5%. Similar to other outcomes, the rates of renal failure varied by extent, ranging from 4% in DTAA and extent I TAAA repairs to 10% in extent II TAAA repairs.

FOLLOW-UP

Acute aortic dissection is one of the most common catastrophes involving the aorta. Dissection of the aorta is characterized by the separation of the aortic media by pulsatile blood, with variable extents of proximal and distal extension along the aorta and its branches. The process of dissection creates a false lumen in the aortic wall that parallels the aortic true lumen. In the majority of cases, a primary intimal tear initiates the dissection and allows blood flow communication between the true and false lumens, which are separated by a dissection flap or septum. Because this acute event is rarely associated with a preexisting aneurysm and the aortic intima (true lumen)

is actually smaller than normal, the older term *dissecting aneurysm* is misleading and inappropriate; to be semantically correct, an aortic dissection should be called a *false aneurysm*. A thorough understanding of the pathophysiology of aortic dissection is critical for prompt diagnosis and effective management in the acute setting. On the other hand, aortic dissection in its chronic phase is responsible for a substantial proportion of thoracic aortic disease and aortic rupture due to false aneurysmal degeneration of the false lumen. Numerous advances in diagnostic modalities, medical and surgical treatment, and long-term management have changed the prognosis for

patients with this lethal condition. This chapter summarizes current knowledge regarding the diagnosis and treatment of Stanford type A aortic dissection.

HISTORICAL NOTE

The observations by Morgagni in 1761 were followed by multiple early anatomic and postmortem reports describing aortic dissection, including the famous autopsy report on King George II of England in 1776.¹ In 1802, Maunoir, describing this disease, used the term *dissection*.² Almost 20 years later, René Laennec coined the term *aneurysme dissequant*, or dissecting aneurysm, believing that this entity represented the early stage of a saccular aneurysm.³ Later, in 1863, Peacock published a comprehensive review of 80 cases of aortic dissection.⁴ Until the last half of the twentieth century, the diagnosis of aortic dissection was almost exclusively an autopsy finding. Antemortem diagnosis was made in only 6 of 300 cases reviewed by Shennan in 1934.⁵ The use of contrast angiography for the diagnosis of aortic dissection was reported by Paullin and James.⁶ The first attempt to treat this condition was described in 1935 by Gurin and colleagues,⁷ who used surgical iliac artery fenestration to relieve lower extremity ischemia. Although quickly abandoned, cellophane wrapping of the dissected aorta was also attempted to prevent rupture.⁸ In 1955, DeBakey and associates⁹ launched the modern era of surgical management with graft replacement of the dissected aorta. Subsequently, the same group introduced the use of cardiopulmonary bypass during clamping of the descending thoracic aorta.¹⁰ The first large clinical series of patients with an aortic dissection was published in 1958 by Hirst and colleagues¹¹; analyzing 505 cases allowed these authors to emphasize the high mortality rate and the glaring rarity of antemortem diagnosis at that time. The modern medical approach to aortic dissection with use of pharmacologic agents to diminish aortic dP/dt (anti-impulse therapy) was introduced by Wheat and associates in 1965.¹² The venerable DeBakey type I, II, III classification of aortic dissection was introduced the same year. The simplified Stanford classification system (type A or type B) based on pathophysiologic characteristics was proposed in 1970 by Daily and colleagues.^{13,14} Since then, other important advances have followed, such as less invasive and more accurate diagnostic modalities, improved anesthetic methods, safer extracorporeal perfusion techniques, profound hypothermic circulatory arrest for thoracic aortic arch surgery (introduced by Griep and coworkers¹⁵ from Stanford in 1975), improved and safer prosthetic vascular grafts, and refinement of cardiovascular surgical techniques.

CLASSIFICATION

It is important to understand and to apply accurately the classification of aortic dissection in order to treat patients most appropriately and to compare rigorously the results of various medical and surgical therapeutic interventions reported from different institutions. Considerable

confusion about classifying aortic dissections has arisen in the past. Numerous systems have been proposed, beginning in 1955 with nine categories initially suggested by DeBakey and associates.⁹ The more widely used DeBakey type I, type II, and type III three-category classification scheme was introduced in 1965¹⁴; importantly, DeBakey modified this scheme in 1982¹⁶ to conform with the Stanford A/B functional criteria based on whether the ascending aorta is involved, regardless of the location of the tear and distal extent of dissection. Despite the use of different labels, a consensus has emerged concerning the essential elements of a common functional classification system of aortic dissection. The key point of all classification systems used today is the presence or absence of involvement of the ascending aorta, regardless of the location of the primary intimal tear and irrespective of the antegrade extension of the dissection process.¹⁷ The simplified Stanford classification approach as proposed by Daily and associates¹³ in 1970 has gained broad acceptance during the past 44 years. If the dissection involves the ascending aorta, it is a Stanford type A, which corresponds to a DeBakey type I,¹⁶ University of Alabama “ascending,”¹⁸ Massachusetts General Hospital “proximal,”¹⁹ and Najafi “anterior” dissection.²⁰ Both DeBakey type I and type II dissections involve the ascending aorta; type I extends beyond the innominate artery, whereas type II is confined just to the ascending aorta. If the ascending aorta proximal to the innominate artery is not involved in the process, the dissection is called a Stanford type B, DeBakey type III, descending, distal, or posterior dissection (Fig. 70-1), even though many of these patients have some limited extent of retrograde dissection involvement in the arch, a point that is not broadly appreciated. A subtype of dissection in which the primary intimal tear is in the descending aorta or even farther distal, yet the dissection process propagates in a retrograde fashion to involve the arch and ascending aorta, was originally termed a *DeBakey type III-D* by Reul and colleagues²¹ in 1975, but now is simply termed a *retro-A dissection*. Retro-A dissections constitute approximately 6% of all type A dissections,²² and recently they have been seen more frequently as a complication of stent-graft descending thoracic endovascular aortic repair (TEVAR).

This functional classification approach reflects the pathophysiology of aortic dissection, considering that involvement of the ascending aorta is the principal predictor of the biological behavior of the disease process and the most common fatal complications; moreover, it simplifies diagnosis because it is easier to identify involvement of the ascending aorta accurately than to determine the exact site of the primary intimal tear (or tears) or the extent of propagation of the dissection process. Furthermore, the Stanford classification system facilitates clinical decision making and expedites definitive management. Patients with acute Stanford type A dissections should be treated surgically in essentially all cases; individuals with Stanford type B dissections can be treated with open surgical intervention, with an endovascular TEVAR, or with medical management, depending on the presence or absence of major complications. More specifically, patients with type A dissections require a median sternotomy, total cardiopulmonary bypass (CPB), and

FIGURE 70-1 ■ Schematic illustration of the Stanford classification system of aortic dissections. The three examples in the top row are all type A aortic dissections because the ascending aorta is involved. The primary intimal tear can be located in the ascending aorta (A), in the transverse arch (B), or in the descending thoracic aorta (C). This last example is now called a *retro-A dissection* and is equivalent to a type III-D dissection. The dissections in (D) and (E) are type B dissections; whether the tear is in the descending thoracic aorta or the arch, the ascending aorta is not involved. The last example (F) is an isolated arch dissection without retrograde or antegrade propagation; these are rare. (From Miller DC: Surgical management of aortic dissections: indications, perioperative management, and long-term results. In Doroghazi RM, Slater EE, editors: *Aortic dissection*, New York, 1983, McGraw-Hill, p 196.)

profound hypothermic circulatory arrest (PHCA); those with type B dissections are approached surgically using a left posterolateral thoracotomy, total CPB with PHCA, partial CPB, or isolated left heart bypass.

Aortic dissections diagnosed within 14 days of the onset of presenting symptoms are defined as acute; those diagnosed more than 14 days after onset are classified as chronic dissections.²³⁻²⁵ According to the International Registry of Acute Aortic Dissection (IRAD) investigators,²⁴ the cumulative mortality after acute type A and type B dissection treated medically reached a plateau after the fourteenth day after presentation, demonstrating the prognostic importance of this venerable but arbitrary 14-day time distinction (Fig. 70-2). DeBakey and colleagues¹⁶ introduced the term *subacute* to describe dissections between 2 weeks and 2 months old, but this distinction has been rarely used; however, the term *subacute* has recently gained popularity because of the use of TEVAR and can mean anything between 2 weeks and 6 or more months. Its use should be rejected because it is ambiguous.

During the past two decades, advances in vascular imaging technology have led to increasing recognition of intramural hematoma (IMH) and penetrating atherosclerotic ulcers (PAUs) as distinct pathologic variants in the

spectrum of acute aortic diseases, which can evolve into classic aortic dissection.^{26,27} Both are characterized by the absence of the classic intimal flap dividing the aorta into true and false channels. IMH can be caused by an ulcer penetrating into the internal elastic lamina or can occur spontaneously without any intimal disruption. IMH can involve the ascending aorta (type A IMH) as well as the descending aorta (type B IMH). On occasion, IMH can suddenly evolve into classic aortic dissection with blood flow in both lumens,²⁸ as different phases of a dynamic aortic pathologic process. PAUs occur most commonly in the descending thoracic aorta in older patients. Distinguishing IMH (with or without a PAU) or PAU from classic aortic dissection is critical because the pathophysiologic process, clinical behavior, prognosis, and management of these lesions can differ,^{29,30} depending on which segment of the aorta is involved and the patient's symptomatic status.

EPIDEMIOLOGY

Aortic dissection is seen in all age groups, although the majority of the cases occur between the ages of 50 and 69 years. In a series of 464 patients reviewed in the IRAD registry, mean age was 63 years.²⁴ Two thirds of aortic dissections involve the ascending aorta (Stanford type A) and a third involve the descending aorta (Stanford type B).²⁴ Typically, patients with type B dissection are older than those with type A dissection.^{10,24} Dissection in patients younger than 40 years typically is a type A dissection. According to the IRAD investigators, younger patients with acute aortic dissections are less likely to be hypertensive and are more likely to have Marfan syndrome, bicuspid aortic valve, some other connective tissue disorder, or prior aortic surgery.³¹ In all studies, there is a clear male predominance with an estimated male-to-female ratio ranging from 2:1 to 3:1. Although less frequently affected by acute aortic syndromes, women are older at the time of diagnosis with a mean age of 67 years and have worse outcomes, perhaps due to atypical symptoms and delay in diagnosis.^{24,32} Hirst and colleagues¹¹ found a higher incidence of aortic dissection in African Americans, which might be related more to hypertension than to any intrinsic racial pathologic weakness of the aorta. Similarly, a high prevalence of hypertension may also explain why the incidence of aortic dissection and its variants is higher in Japan and other Asian countries.

The true incidence of aortic dissection is difficult to determine because many patients die without the correct diagnosis being made antemortem.³³ It is not widely appreciated that acute aortic dissection is the most common clinical catastrophe involving the aorta. Moreover, its incidence has been increasing in the industrialized world, in part because of increasing life expectancy and more years exposed to elevated blood pressure. In a 1964 Danish study of 6480 autopsies covering 90% of a regional population, the incidence of acute aortic dissection was 5.2 per million population per year, higher than the incidence of ruptured abdominal aortic aneurysm (3.6 per million population per year) and more than four

FIGURE 70-2 ■ Thirty-day mortality according to dissection type and management in the International Registry of Acute Aortic Dissection. (From Hagan PG, Nienaber CA, Isselbacher EM, et al: The International Registry of Acute Aortic Dissection [IRAD]: new insights into an old disease. *JAMA* 283:897–903, 2000.)

times the prevalence of ruptured thoracic aortic aneurysm (1.2 per million population per year).³⁴ In the seminal 1958 pathologic series by Hirst and associates,¹¹ acute aortic dissection was found in 1% to 2% of autopsies. In the 1970s, it was estimated that the incidence of acute aortic dissection in an urban population containing many African Americans in the southeastern United States might be as high as 10 to 20 cases per million population per year,³⁵ or approximately 2000 to 4500 new cases each year.³⁶ According to a review of all thoracic aortic diseases among the residents of Olmsted County, Minnesota, between 1980 and 1994, the annual incidence of acute aortic dissection was estimated at 3.5 per 100,000 person-years.³³ More recently, in a comprehensive review of the entire Swedish national health-care registry during a 15-year period, it was observed that the incidence of thoracic aortic aneurysm and dissection had increased substantially between 1987 and 2002; specifically, the incidence of thoracic aortic disease rose by 52% in men and by 28% in women during this period to reach 16.3 cases per 100,000 per year and 9.1 cases per 100,000 per year, respectively.³⁷ In general, these prevalence estimates undoubtedly underestimate the real incidence because they do not capture patients who die suddenly of a complication of aortic dissection and who are presumed to have succumbed to coronary disease or an arrhythmic event in the absence of a postmortem examination; importantly, this was not the case in the report from Sweden, where many dissections were identified only at the time of forensic autopsy, which is still performed almost universally in that country. Most physicians tend to think that ruptured abdominal aortic aneurysms are more common; this misconception comes from the fact that ruptured abdominal aortic aneurysm is

diagnosed correctly more often than is acute aortic dissection.

NATURAL HISTORY

According to the historical autopsy analyses, untreated acute aortic dissection is a highly lethal event. In the study by Shennan published in 1934,⁵ 40% of patients with dissection involving the ascending aorta died immediately, 70% within the first 24 hours, 94% within the first week, and 100% within 5 weeks. In 1967, Lindsay and Hurst³⁸ reported that one third of patients sustaining an acute aortic dissection died within 24 hours, 50% within 48 hours, 80% within 7 days, and 95% within the first month. In patients with chronic dissection, only 15% were still alive after 5 years. In patients with dissection involving the descending thoracic aorta (Stanford type B), 25% had died 1 month after onset. Later, Anagnostopoulos and coworkers,³⁹ in a large collected series of 963 cases of patients not surgically treated with aortic dissection of all types, reported a cumulative mortality of 70% at 1 week and 90% at 3 months, but as in other retrospective investigations the true patient denominator was unknown.

Most patients with untreated acute type A dissection die of intrapericardial rupture culminating in cardiac tamponade; other causes of death include acute aortic valvular regurgitation resulting in left ventricular failure, coronary ostial compromise causing acute myocardial ischemia, occlusion of aortic branches supplying the cerebral or visceral circulation, and free aortic rupture. Patients with untreated acute type B dissection usually die of aortic rupture or of distal end-organ malperfusion (occlusion

of major aortic branches resulting in ischemic injury to vital abdominal organs, termed thoracoabdominal malperfusion).²³ In the Stanford experience, lower extremity ischemia at presentation did not significantly increase surgical mortality risk, whereas occlusion of major abdominal tributaries resulting in renal or splanchnic ischemia was associated with very high mortality rates.^{40,41}

Only 10% of acute dissections are estimated to “heal” spontaneously, eventually becoming chronic dissections. Distal reentry sites are found in nearly all cases, allowing decompression of the false lumen.^{42,43} After acute aortic dissection, the false lumen usually remains patent but may thrombose rarely, depending mainly on the presence, size, and site of distal false lumen reentry sites. When the false lumen remains patent, it is prone to progressive expansion over time, resulting in the formation of a false aneurysm. It is noteworthy that a large fraction of acute serious or fatal dissection complications are caused by a *non-reentering* false lumen, which compromises distal blood flow by extrinsically narrowing or occluding the true lumen.

PREDISPOSING FACTORS

Hypertension

In patients with aortic dissection, the prevalence of hypertension varies between 45% and 80%,^{10,23,24,43,44} being highest in patients with acute type B dissection. Untreated hypertension promotes medial smooth muscle cell degeneration and other changes in the aortic wall, which may increase the susceptibility for aortic dissection.⁴⁵ Although there is no evidence to suggest that hypertension initiates the actual process, it is a major risk factor.

Connective Tissue Disorders

Heritable connective tissue disorders such as Marfan, Ehlers-Danlos, and Loeys-Dietz syndromes are associated with an increased risk of aortic dissection. The Marfan syndrome is inherited as an autosomal dominant trait and is characterized by mutations of the *FBN1* gene encoding the glycoprotein fibrillin 1, which is a major component of elastic fibers of the extracellular matrix in various organs.^{46,47} In addition to cardiovascular manifestations, including mitral valve prolapse, progressive aortic root dilation, aortic valve regurgitation, and aortic dissection, these patients can have several other ocular and musculoskeletal abnormalities. The diagnosis of Marfan syndrome is made according to the revised 2010 Ghent criteria (major and minor), which characterize the involvement of different organ systems, as well as genetic testing identifying a *FBN1* mutation.^{48,49} When a patient demonstrates the classic Marfan syndrome phenotype, the diagnosis is rarely in doubt; however, many patients have only some of the characteristic phenotypic features (variable penetrance), including aortic root dilation with or without aortic valve regurgitation, which has been called the *forme fruste* of Marfan syndrome.⁴⁶ Aortic-related complications, including acute dissection and

rupture, are the leading causes of death in patients with Marfan syndrome. If a patient with Marfan syndrome has a family history of aortic dissection or other aortic catastrophe at an early age, the risk of dissection or rupture is considerably higher.^{47,49} The prevalence of Marfan syndrome in patients presenting with acute aortic dissection ranges between 5% and 12%.^{10,24,44,50}

Patients with Ehlers-Danlos syndrome, particularly those with type IV (vascular type) Ehlers-Danlos syndrome, which is transmitted in most cases as an autosomal dominant trait, have arterial weakness of all large and muscular arteries; type IV Ehlers-Danlos syndrome is characterized by a procollagen type 3 (COL3A1) abnormality and an increased risk of aortic dissection or spontaneous rupture of peripheral arteries or a hollow abdominal viscus.⁵¹ Aortic rupture has also been reported in patients with Ehlers-Danlos syndrome type I and type VI. Extremely fragile arteries are found in patients with Ehlers-Danlos syndrome, and vascular procedures, including simple arterial puncture and suture repair, can be fraught with devastating complications.⁵² The diagnosis of (vascular type) Ehlers-Danlos syndrome is based on genetic testing identifying a mutation in the gene *COL3A1* coding for type III procollagen.^{49,53,54}

Loeys-Dietz syndrome is a more recently recognized autosomal dominant connective tissue disorder characterized by premature arterial aneurysms (typically aortic root aneurysm) and aortic dissection along with diffuse peripheral arterial tortuosity. It is caused by heterogeneous mutations in the genes encoding transforming growth factor β receptors 1 and 2 (TGFB1 and TGFB2), and the diagnosis is confirmed through identification of these mutations.^{49,55} Phenotypic features of Loeys-Dietz syndrome include hypertelorism, bifid uvula or cleft palate or both, hyperlucent skin, and generalized arterial hypertortuosity, especially of the extracranial carotid or iliac arteries. In these patients, the risk of aortic rupture and aortic dissection exceeds that of any other known connective tissue disorders. In addition, aortic rupture and dissection occur at a younger age (even in infants) and at small (almost normal) aortic diameters.

More recently, a genetic basis of nonsyndromic familial thoracic aortic aneurysms and dissection has been defined involving multiple defective genes. Specifically, several gene mutations have been identified causing various defects in cell signaling pathways (TGFB2 mutations different than in Loeys-Dietz syndrome) and protein synthesis of components in the contractile apparatus of vascular smooth muscle cells (MYH11 and ACTA2 mutations), resulting in thoracic aortic aneurysms and aortic dissection occurring at aortic diameter less than 5 cm.^{43,49,56}

Congenital Abnormalities

Congenital heart problems, such as bicuspid aortic valve and coarctation of the aorta, are associated with an increased risk of aortic dissection compared with that in the general population. In an analysis of 186 autopsies of patients who died of type A aortic dissection, it was found that the prevalence of unicuspid or bicuspid aortic valves was 9%.⁵⁷ The risk of perioperative and late postoperative

dissection is also increased in patients with a bicuspid aortic valve after any type of cardiac surgery, especially in patients with dilation of the ascending aorta.^{49,58,59} Aortic dissection predominantly involves the ascending aorta in patients with coarctation and the transverse arch is relatively hypoplastic,⁶⁰ and the dissection may not propagate beyond the aortic isthmus. Simultaneous management of an acute type A aortic dissection in patients with uncorrected severe coarctation is challenging and may require modification of the CPB arterial cannulation strategy and occasionally the use of an extra-anatomic thoracic aortic graft to bypass the coarctation.^{61,62}

Iatrogenic Injury

Aortic dissection is a rare complication of cardiac catheterization and other percutaneous diagnostic and therapeutic interventional techniques involving manipulation of catheters inside the thoracic aorta.⁶³ Catheter and guidewire injuries are usually self-limited, localized subintimal dissections that only rarely require surgical intervention. On the other hand, life-threatening iatrogenic dissections can occur during endovascular device deployment (TEVAR or transfemoral percutaneous aortic valve replacement) or open surgical procedures; among 7000 cardiac operations, iatrogenic aortic dissection complicated 0.3% of cases.⁶⁴ These can be due to ascending aortic cannulation, retrograde dissection after femoral artery cannulation, aortic cross-clamp or partial occluding clamp injury, and intimal injury at the site of a proximal bypass graft anastomosis.^{63,65} The incidence of iatrogenic perioperative type A aortic dissection is higher in patients undergoing off-pump coronary artery bypass grafting, which was attributed to multiple ascending aortic manipulations for construction of the proximal anastomoses.⁶⁶

Pregnancy

In women younger than 40 years, approximately 50% of dissections occur during the third trimester or during labor and delivery; a substantial proportion of these women have connective tissue disorders, such as Marfan syndrome, or a bicuspid aortic valve associated with a dilated tubular segment of the ascending aorta.^{67,68} The hemodynamic and hormonal alterations of pregnancy, culminating in the third trimester, are thought to be the causes of dissection in susceptible individuals.

Illicit Drug Related

One of the cardiovascular complications of cocaine use, particularly crack cocaine inhalation, is acute aortic dissection.^{69,70} Aortic dissection in this setting occurs presumably as a consequence of abrupt, severe hypertension and catecholamine release, and this diagnosis should be considered in cocaine or methamphetamine abusers presenting with chest pain.

Other Associations

Aortic dissections also occur more frequently than in the general population in patients with autosomal dominant

polycystic kidney disease, Turner syndrome, Noonan syndrome, and Alagille syndrome.^{49,71} Inflammatory diseases such as Takayasu arteritis, giant cell arteritis, Behçet disease, autoimmune disorders such as systemic lupus erythematosus, and infection of the aorta, such as syphilis, have been rarely associated with acute aortic dissection.^{42,43,49}

PATHOPHYSIOLOGY AND PATHOLOGIC FINDINGS

Medial Degeneration

In 1929, Erdheim⁷² was the first to describe what he called “cystic medial necrosis,” a nonspecific pathologic process involving medial smooth muscle cell loss, elastic lamellar disruption, and acid mucopolysaccharide accumulation within the aortic media. This abnormal architecture is believed to lead to changes in the distribution of both circumferential wall stress and shear stress in the aortic media, potentially leading to an intimal tear.⁷³ The word *cystic* is actually a misnomer, because these medial lesions do not form true cysts (they are not lined by epithelial cells). The term *necrosis* is also incorrect because it is singularly absent. In young patients (particularly those with a heritable connective tissue disorder), the elastic elements of the aortic media are disrupted and disorganized; in older individuals, it is the smooth muscle elements of the aortic media that are abnormal because of aging and hypertension,^{74,75} and probably represent changes associated with repeated aortic wall injury and repair. Thus, the well-known moniker “cystic medial necrosis” should be abandoned and replaced by more specific terms relating to alterations of the elastic fibers (“elastic type”) and smooth muscle cells (“smooth muscle type”) in the media in younger and older patients, respectively. In patients with inherited connective tissue disorders, such as Marfan syndrome, pathologic examination of the aortic wall frequently revealed pronounced medial degeneration, with severe loss of elastic lamellae and accumulation of mucoid substance within the media. These young patients typically have an acute type A dissection. On the other hand, in older individuals, type B dissections are more common and are associated with medial degeneration characterized by loss of smooth muscle cells. It was proposed that the coexistence of activated T lymphocytes and macrophages and markers of apoptotic vascular cell death in the aortic media of patients with aortic dissection may contribute to the two pathways leading to medial degeneration, namely, loss of vascular smooth muscle cells and degradation of the extracellular matrix.⁷⁶ Increased contents of collagen types I and III as well as increased activity of connective tissue growth factor have been observed in the media and adventitia of patients with aortic dissection⁷⁷; these phenomena are likely to be responsible for the reduced aortic distensibility and compliance. Another contributing factor to progressive degradation of the extracellular matrix is excessive activation of matrix metalloproteinases, particularly matrix metalloproteinase 9, which are zinc-dependent proteolytic enzymes that can disrupt the

balance composition of vascular smooth muscle cells and extracellular matrix proteins.⁷⁸ Specific nucleotide polymorphism of the gene encoding matrix metalloproteinase 9, more specifically, the presence of the -8202A/G allele, seems to be associated with an increased risk of aortic dissection.⁷⁹

Primary Intimal Tear

Most authorities believe that the initiating event in aortic dissection is a tear in the intima allowing blood to enter the aortic wall that culminates in progressive separation of the medial layers of the aorta (elastic and circumferential smooth muscle fibers) with propagation of the dissecting hematoma. The primary intimal tear allows communication between the true aortic lumen and the false lumen. Only 2% to 4% of aortic dissections do not have an identifiable primary intimal tear and are usually confined to the descending thoracic aorta.¹¹ Rarely in patients with connective tissue disorders, a localized intimal disruption can be present without extensive undermining of the intima, pseudoaneurysm development, or any false lumen,⁸⁰ what we colloquially call “intimal stretch marks.” If they are associated with a localized hematoma within the wall, they have a “mushroom cap” appearance. Whether an intimal tear is the precipitating event in all aortic dissections is still debated.⁷³ IMH owing to rupture of the vasa vasorum is another potential but infrequent initiating event leading to frank dissection. Rupture of the intima usually happens at points of maximal wall stress along the thoracic aorta. Intimal tears are usually transverse in orientation and typically involve one half to two thirds of the aortic circumference. Infrequently, total disruption of intimal continuity with a complete circumferential tear can lead to intimo-intimal intussusception and mechanical obstruction of blood flow⁸¹ because of gross prolapse of the circumferential intima. In type A dissections, the majority of intimal tears (60% to 70%) are located in the ascending aorta, usually just distal to the sinotubular junction (Fig. 70-3).^{11,82,83} In 10% to 20%, the intimal tear is located in the aortic arch, most commonly on the lesser curvature.^{84,85} The intimal tear can also originate in the proximal one third of the descending aorta, near the aortic isthmus (“retro-A dissection”). In less than 5% of cases, the intimal tear can be located in the abdominal aorta, and the dissection will either be confined to the abdominal aorta or propagate in a retrograde fashion to involve the ascending thoracic aorta.^{86,87}

Propagation and Reentry

Within the aortic wall, the false lumen is situated between the inner two thirds and the outer one third of the aortic media. On pathoanatomic examination, the dissected aorta is a false aneurysm, because the aortic intima containing the true lumen is not dilated and actually is smaller than normal. Once initiated, aortic dissections usually propagate antegrade or “downstream” but may also extend in a retrograde direction. The dissection often proceeds in a spiral fashion down along the aorta. Propagation of the dissection depends on several factors,

FIGURE 70-3 ■ Location of the primary intimal tear in a series of 168 patients who underwent operative repair of (A) acute type A aortic dissection ($n = 169$) and (B) acute type B aortic dissection ($n = 29$). (From Lansman SL, McCullough JN, Nguyen KH, et al: Subtypes of acute aortic dissection. *Ann Thorac Surg* 67:1975–1978, 1999.)

including rate of increase of aortic systolic pressure (or aortic dP/dt), magnitude of aortic diastolic elastic recoil and stiffness, mean and peak arterial pressure, and aortic wall integrity and strength.^{42,43,88,89} The mainstay of medical treatment of aortic dissection, as described by Wheat and Palmer in 1965, is directed at reducing aortic dP/dt , called *anti-impulse therapy*.¹² In the ascending aorta, the false lumen usually occupies the right anterior portion; in the arch, the false lumen usually is located along the greater curvature and may extend into the innominate, left carotid, or left subclavian arteries. In the descending and abdominal aorta, the false lumen often runs along the anterior and lateral aortic walls, frequently incorporating the take-off of the left renal artery.¹¹ Distal progression of the dissection may be limited by extensive atherosclerosis or anatomic constraints such as aortic coarctation, infrarenal abdominal aortic aneurysm, or abdominal aortic graft anastomosis.⁶⁰ Otherwise, in young individuals the dissection almost always involves the entire thoracic and abdominal aorta and extends into the iliac arteries. Limited Stanford type A, DeBakey type II dissections are rare in our experience. In patients surviving the acute episode, the false lumen usually remains patent but rarely may thrombose spontaneously. The presence of distal reentry sites or fenestrations contributes to persistent patency of the false lumen. Partial or complete thrombosis of the false lumen may allow “healing” of the aorta; conversely, if the false lumen reenters distally and stays patent, it is prone to progressive false aneurysmal enlargement. A patent distal false lumen is observed in up to 90% of patients after surgical repair of acute type A dissections and may portend an adverse prognosis associated with a higher incidence of late “downstream” false aneurysmal degeneration.^{90,91} Reentry sites are usually multiple and frequently occur at the ostia of sheared off branches, such as the intercostal, visceral, renal, or iliac arteries. Reentry into the true lumen,

FIGURE 70-4 ■ Schematic illustration of classic aortic dissection with a distinct intimal flap separating the true and false lumens (*left*), penetrating atherosclerotic ulcer with a localized intimal lesion burrowing into the media and leading in some cases to localized dissection (*middle*), and intramural hematoma without intimal lesion (*right*). (From Coady MA, Rizzo JA, Elefteriades JA: Pathologic variants of thoracic aortic dissections. Penetrating atherosclerotic ulcers and intramural hematomas. *Cardiol Clin* 17:637–657, 1999.)

described by Peacock in 1843 as “an imperfect natural cure of the disease,”¹ allows decompression of the false lumen and is the rationale behind surgical and percutaneous flap fenestration techniques.^{92,93}

Intramural Hematoma

In 1920, Krukenberg⁹⁴ first described aortic IMH as a “dissection without intimal tear.” IMH is believed to originate from rupture of the vasa vasorum within the outer third of the media, resulting in the circumferential accumulation of blood (Fig. 70-4), with no apparent intimal defect visualized on imaging studies.²⁹ IMH can occur spontaneously in predisposed individuals (e.g., older and hypertensive patients) or be a secondary phenomenon after the rupture of an atheromatous plaque through the internal elastic lamina and the formation of a penetrating atherosclerotic ulcer allowing extravasation of blood into the aortic wall (see Fig. 70-4).²⁷ The natural history of these lesions was not well characterized until the last two decades. The evolution of IMH may either be benign, with a stable clinical course and eventual healing, or a progressive, often fatal disease, with extension, evolution into classic aortic dissection, aneurysmal degeneration, or aortic rupture.^{28–30,95} In recent years, it was recognized that IMH involving the ascending (type A IMH) or descending (type B IMH) aorta can occasionally portend a different clinical course from that of classic aortic dissection, especially if it is detected incidentally in asymptomatic patients undergoing cross-sectional imaging. Conversely, patients with acute severe chest pain are more prone to disease progression and aortic rupture, similar to those with full-blown acute dissections, especially in the presence of an associated deep penetrating ulcer.^{26,30,95,96} We believe that IMH of the ascending aorta usually has a malignant prognosis almost identical to that of acute type A aortic dissection, and these patients should be treated accordingly.

Aortic Branch Compromise

Peripheral branch vessel ischemia or malperfusion arises when the dissection process compromises blood flow to various aortic tributaries through several mechanisms, including extrinsic compression of the true lumen by the

FIGURE 70-5 ■ Examples of branch artery involvement in aortic dissection. Continued adequate perfusion of an aortic tributary is illustrated in (A), (B), and (F); however, perfusion is from the true lumen in (A) and (B) and through the false lumen in (F). Obstruction of an aortic tributary owing to extrinsic compression is shown in (C) and (D), whereas compromise of the ostium of the true lumen with secondary thrombosis is shown in (E). In (F), reentry of the dissection into the branch vessel has created an intimal flap. This can become a permanent situation if the flap heals to the opposite wall of the artery in the chronic phase, thus rendering this branch solely dependent on false lumen perfusion. (From Miller DC: Surgical management of aortic dissections: indications, perioperative management, and long-term results. In Doroghazi RA, Slater EE, editors: *Aortic dissection*, New York, 1983, McGraw-Hill.)

pressurized false lumen (particularly a false lumen that does not reenter), an intimal flap compromising the orifice of the branch artery (Fig. 70-5), and occlusion of the tributary if the dissection continues into the branch because of false lumen extrinsic compression of the true lumen distally. A useful pathophysiologic classification of aortic branch compromise was proposed by Williams and associates⁹⁷: *static obstruction* occurs when the dissection flap extends into a branch vessel, resulting in mechanical compromise of flow; *dynamic obstruction* occurs when the dissection flap narrows the aortic true lumen above the branch because of a large false lumen or when the flap prolapses into the vessel origin. As the dissection progresses in a spiral fashion along the aorta, some aortic branches may be spared and continue to be perfused by the true lumen, whereas other arteries may be perfused exclusively from the false lumen after being sheared off; in this latter scenario, the affected branch subsequently becomes permanently dependent on the false lumen for perfusion. In some cases, compression by the false lumen may almost eliminate the entire aortic true channel (true lumen collapse or true lumen obliteration) with resultant

severe distal thoracoabdominal malperfusion.^{97,98} The pattern of branch artery involvement and the degree of perfusion compromise determine the clinical presentation, which is enormously variable and often leads to delay before the correct diagnosis is established. Indeed, acute aortic dissection has been called “The Great Masquerader” because the symptoms can mimic those of many other acute illnesses. In the large autopsy series by Hirst and colleagues,¹¹ the most commonly affected aortic branches were the iliac arteries, followed (in descending order) by the innominate, left common carotid, left subclavian, coronary, renal, superior mesenteric, and celiac axis.

CLINICAL MANIFESTATIONS

Patient Characteristics

Patients with type A dissections are usually younger, including those with Marfan syndrome and other heritable connective tissue disorders or congenital aortic valve disease, whereas type B dissection is usually seen in middle-aged and older men. Either type of dissection can occur in women, usually at an older age, but is exceptionally rare in children and teenagers.^{10,24,32,43} Older patients usually have coexisting medical conditions, including hypertension and generalized arteriosclerosis, as well as associated medical comorbidities, such as cerebrovascular, cardiac, pulmonary, and renal disease.

Acute Type A Dissection

Pain

The most common presenting symptom of aortic dissection is severe chest pain, usually originating in the anterior chest or in the interscapular region, which correlates with the location of the dissection. The onset of pain is typically abrupt and most severe at onset, described as sharp or tearing, and it is thought to be due to stretching of the aortic adventitial nerve fibers by the dissection; the pain typically then migrates down the chest and into the abdomen. Persistence of pain suggests continuing expansion within the chest or distal propagation. Differentiation of the chest pain associated with acute aortic dissection from other causes, such as acute myocardial ischemia, pulmonary embolism, or pericarditis, is critical in the initial evaluation of these patients to allow prompt management. The presence of additional clinical findings, such as a diastolic murmur, blood pressure difference between arms or legs, and new neurologic deficit, increase the likelihood of an acute type A aortic dissection in the presence of chest pain.⁹⁹ In some patients, the initial pain will disappear either spontaneously or with institution of medical treatment; recurrent pain thereafter is an ominous sign suggesting impending aortic rupture or continuing downstream extension of the dissection.¹⁰⁰ On occasion, acute dissection can be painless. A high clinical index of suspicion is required for patients with aortic dissection as its manifestations can mimic any other acute medical or surgical illness. In an IRAD report,

pain of abrupt onset was the presenting symptom in 85% of patients, and the most common site was the chest. It was located anteriorly in 71% of patients with type A dissection, but 47% and 22%, respectively, of these patients reported back pain and abdominal pain.^{24,43}

Systemic Manifestations

One third to half of all patients with acute aortic dissection demonstrate signs and symptoms secondary to cardiac and other organ system involvement.* Aortic branch compromise, aortic rupture or leak, and compression of adjacent organs by an expanding false lumen are the most common mechanisms responsible for complications of aortic dissection.

Cardiovascular Manifestations

Patients with acute aortic dissection appear pale and poorly perfused peripherally but generally have elevated blood pressure because of preexisting arterial hypertension, high circulating levels of catecholamines, pain, or renal artery compromise by the dissection. Blood pressure must be recorded in both arms, and a thorough evaluation of peripheral pulses in all four extremities is essential. Hypotension in patients with acute dissection suggests cardiac tamponade¹⁰³ or impending rupture; shock is usually due to intrapericardial rupture with tamponade, intrathoracic rupture, or acute left ventricular failure secondary to myocardial ischemia or acute, severe aortic valve regurgitation. Aortic rupture is the most frequent cause of death in the acute setting¹¹; the most common site of rupture is near the site of the primary intimal tear.⁸⁹ Ascending aortic and arch involvement can rupture into the pericardial cavity or the mediastinum; however, rupture of a more distal thoracic aortic segment is also possible with exsanguination into the left pleural space or rarely the retroperitoneum. Aortic valve regurgitation is present in 20% to 50% of patients with acute type A dissection.^{10,23-25,104} Extension of the dissection retrograde into the aortic root with shearing off of one or more aortic valve commissures causes diastolic prolapse of the cusps. A murmur of aortic regurgitation is heard in 25% to 45% of patients and may be associated with an S₃ gallop and pulmonary rales.^{24,42} Acute, severe aortic regurgitation leading to left ventricular failure is the second most common cause of death in patients with type A dissection, after aortic rupture. Less commonly, proximal extension of the dissection into the coronary ostia can impair coronary perfusion and cause myocardial ischemia or infarction.¹⁰⁵ In this situation, involvement of the right coronary artery is more common than involvement of the left coronary artery, and the electrocardiographic findings may include changes consistent with acute inferior myocardial infarction. Contained or frank aortic rupture or, more commonly, transudation of fluid from the false lumen through the intact aortic epicardial layer (there is no adventitia because the ascending aorta is an intrapericardial structure) into the pericardial cavity can

*References 10, 24, 42, 43, 99, 101, 102.

lead to pericardial effusion and cardiac tamponade associated with jugular venous distention, Kussmaul sign, paradoxical pulse, or pericardial friction rub. Cardiac tamponade is reported in 10% to 20% of patients with acute type A dissection and mandates emergency surgical intervention.¹⁰³ Rarely, the expanding false lumen may compress surrounding structures, such as the pulmonary artery or the superior vena cava, or rupture into one of the cardiac chambers, resulting in an aorto-atrial or aortoventricular fistula.^{106,107} Heart block can be seen in cases with involvement of the membranous and interatrial septum by a pressurized dissection-related hematoma.¹⁰⁸

Peripheral Vascular Complications

Systemic arterial manifestations of aortic dissection are the result of the propagation of the dissection process leading to aortic branch compromise and ischemia or infarction of various end organs. Approximately 30% of patients initially exhibit symptoms related to acute peripheral arterial compromise or will develop such complications.^{16,101,102,109,110} Clinical manifestations include coma, stroke, paraplegia, upper or lower extremity ischemia, and anuria or abdominal pain due to renal or mesenteric ischemia.

In a historical review of the Stanford University experience with management of aortic dissection associated with acute peripheral vascular complications by Fann and associates,¹⁰² 85 (31%) of 272 patients (128 acute type A, 40 acute type B dissection) had one or more peripheral arterial manifestations. Among these 168 patients, 4% presented with acute carotid occlusion and stroke, 5% had acute paraplegia secondary to spinal cord ischemia, 33% sustained loss of one or more peripheral pulses, 11% had impaired renal perfusion demonstrated angiographically, and 6% had compromised visceral perfusion by angiography. The prevalence of these complications according to type of dissection and the operative mortality after definitive intrathoracic surgical management are summarized in Table 70-1. Those with advanced intra-abdominal ischemia or infarction had a dismal prognosis, but simple loss of a peripheral pulse did not predict higher mortality or morbidity. In the literature, it is essential to differentiate between visceral (or renal) ischemia defined on a clinical or symptomatic basis (the

most important issue) or on an imaging basis, which overestimates the incidence of clinically meaningful complications.

Acute stroke or transient ischemic attack with hemiplegia is the most common neurologic manifestation. These result from cerebral hypoperfusion secondary to aortic arch involvement or obstruction of the true lumen in a carotid or vertebral artery. Stroke or transient ischemic attack usually occurs in patients with an acute type A dissection, and the reported incidence ranges from 3% to 7% in large series.^{16,101,110,111} Beside stroke, altered cerebral perfusion can lead to altered or fluctuating mental status, coma, or syncope in as much as 12% of patients.²⁴ Extensive dissection can compromise perfusion of the spinal cord by shearing off critical intercostal arteries, thereby interrupting flow to the radicularis magna artery and causing paraplegia or paraparesis in 2% to 6% of cases.^{16,101,102} Symptoms related to involvement of peripheral nerves, such as paresthesia and Horner syndrome, are due to peripheral ischemic neuropathy or to direct compression of a nerve by the expanding false lumen. In rare circumstances, stroke, paraplegia, or syncope without chest pain may be the only clinical manifestation of aortic dissection.²⁴

The incidence of renal ischemia owing to acute dissection varies from 5% to 25%.^{43,101,102,110} This wide variability is probably related to methods of detection (ultrasonography, computed tomography, angiography versus autopsy) more than to true population differences. Whether and how it is defined on a clinical or imaging basis is also of paramount importance. Dissection resulting in renal artery compromise may be asymptomatic and remain undetected unless diagnostic imaging studies are performed, but can be associated with oliguria or anuria and worsening renal function. Other clinical manifestations of impaired renal perfusion include refractory hypertension, flank pain, and hematuria. In contrast to previous reports observing that the left renal artery is more frequently involved,¹¹ the right renal artery was more often compromised in our experience¹⁰²; nonetheless, the left renal artery is more frequently fed by the aortic false lumen than by the true lumen.

Aortic dissection involving the visceral arteries leads to mesenteric ischemia or infarction, which is a highly lethal complication. Compromised splanchnic perfusion causing clinical events is relatively uncommon, occurring in less than 5% of cases, although autopsy studies suggest that dissection involvement of the celiac or superior mesenteric arteries is present in more than 10% of patients.^{11,102} At Stanford, the incidence of angiographically defined visceral ischemia was 6% in patients with acute type A dissection. Visceral ischemia portends a grave prognosis,^{101,102} but it can have various clinical presentations ranging from asymptomatic angiographic evidence of visceral hypoperfusion to frank bowel infarction. The cardinal association of abdominal pain out of proportion to the findings on physical examination should lead to prompt consideration of gut ischemia.

Peripheral pulse loss occurs in 30% to 50% of patients with acute type A dissection and 25% of all patients irrespective of dissection type.¹⁰² The clinical course of patients with peripheral limb ischemia is highly variable

TABLE 70-1 Peripheral Vascular Complications and Associated Operative Mortality Rates Among 128 Patients with Acute Type A Aortic Dissection

Peripheral Vascular Complication	Prevalence (n)	Mortality (n)
Stroke	6% ± 3% (7)	14% ± 14% (1)
Paraplegia	6% ± 3% (7)	43% ± 19% (3)
Pulse deficit	38% ± 5% (48)	25% ± 6% (12)
Renal ischemia	12% ± 4% (15)	53% ± 13% (8)
Visceral ischemia	6% ± 3% (8)	50% ± 18% (4)

Data from Fann JI, Sarris GE, Mitchell RS, et al: Treatment of patients with aortic dissection presenting with peripheral vascular complications. *Ann Surg* 212:705–713, 1990.

and dynamic; therefore, frequent comprehensive pulse examinations are important. In the Massachusetts General Hospital experience, one third of these patients experienced either spontaneous resolution of the pulse deficit or a fluctuating clinical picture.¹⁰¹ This phenomenon is thought to be related to spontaneous reentry of flow into the true lumen from the false lumen when the false lumen earlier was non-reentering and compromising the true lumen by means of extrinsic compression. Alternatively, loss of a peripheral pulse can be asymptomatic, especially in the upper extremities. Rarely, proximal descending thoracic aortic obstruction owing to “true lumen collapse” or dynamic “true lumen obliteration” can cause severe ischemia of the entire lower body.⁹⁸

Chronic Type A Dissection

Patients surviving the initial acute phase of acute dissection, surgically treated or not, will be at risk for development of aortic complications in the chronic phase of the disease. Most patients with chronic type A dissection are asymptomatic until they develop problems related to progressive expansion of the downstream aortic false lumen with aneurysmal degeneration, worsening aortic valve regurgitation, aneurysmal degeneration of preserved sinuses of Valsalva, or false aneurysms from previous surgical graft anastomoses. It has been estimated that up to one fourth of patients will develop downstream false lumen aneurysmal degeneration and require reoperation or interventional reintervention within 10 to 15 years after an acute dissection, emphasizing the importance of indefinite, comprehensive follow-up care and serial imaging studies.^{16,90,112-114} Uncommonly, patients who had an asymptomatic acute dissection may present many months to years later with a thoracic aortic false aneurysm discovered incidentally on a chest radiograph or a computed tomographic (CT) scan done for an unrelated problem. Progressive expansion of the false lumen may produce compression, obstruction, or erosion into adjacent mediastinal structures. Therefore, symptoms related to aortic aneurysmal enlargement can include chest pain, dyspnea, wheezing or stridor, hoarseness, dysphagia, superior vena cava syndrome, hemoptysis (aortobronchial or aortopulmonary fistula), and hematemesis (aortoesophageal fistula). Signs and symptoms of heart failure can result if the degree of aortic regurgitation becomes severe. Rarely, late thrombosis of the false lumen can compromise flow in a critical branch perfused solely by the false lumen, resulting in complications such as paraplegia, lower extremity ischemia, new-onset renal failure, refractory arterial hypertension, or abdominal angina (visceral ischemia). Late aortic rupture can occur into the pericardium, bronchi, esophagus, or pleural cavity, causing tamponade or exsanguination. Nonetheless, a large majority of patients with chronic aortic dissection problems remain asymptomatic and are diagnosed incidentally.

DIAGNOSTIC MODALITIES

Prompt and accurate diagnosis of acute aortic dissection is crucial to determine the optimal treatment strategy.

The initial diagnostic step is exercising a high degree of clinical suspicion, which is especially important considering that aortic dissection has been referred to as the great clinical masquerader. Historically, aortography was considered the gold standard for the diagnosis of aortic dissections, but major developments in cardiovascular cross-sectional imaging during the past 35 years have greatly expanded the spectrum of less invasive modalities available for evaluation of thoracic aortic disease. Specifically, CT scanning, transesophageal echocardiography (TEE), and magnetic resonance imaging (MRI) can quickly and accurately confirm the diagnosis of aortic dissection. It is rare that one must resort to angiography today, unless a catheter interventional procedure is being performed for malperfusion. In selecting which imaging study is best, the clinician should keep in mind what information is needed most in patients with suspected acute aortic dissection. As a general rule, the best initial diagnostic imaging study is the one that can be performed most rapidly in any particular hospital.^{43,44,49,99,115-117} In most medical centers, the procedure of choice is either CT or TEE, which can reliably confirm or rule out the suspected diagnosis quickly. The imaging modality determines conclusively whether the dissection involves the ascending aorta (Stanford type A) or is restricted to the descending thoracic aorta and/or arch (Stanford type B). Determining the severity of aortic valve regurgitation and identification of a large pericardial effusion are also important, which reinforces the clinical utility of TEE.¹¹⁸ Last, localization of the primary intimal tear, determination of the extent of the dissection process, status of the false lumen (patent, partially thrombosed, or completely thrombosed), and the presence or absence of aortic branch compromise are additional key features that should be identified. Interestingly, in an IRAD report, two thirds of patients with acute aortic dissection required two or more imaging studies before a definitive diagnosis could be made before definitive management was begun.¹¹⁹

Although chest radiography is neither sensitive nor specific for the diagnosis of aortic dissection, some findings may be suggestive. Widening of the mediastinal silhouette can be present in up to 50% of cases.^{24,99} Other findings can include the displacement of intimal calcification, a localized hump on the ascending aorta or arch, a widening of the aortic knob, a double aortic shadow, and a pleural effusion.¹²⁰ Similarly, electrocardiographic findings, such as ST-segment or T-wave changes, are non-specific, and an abnormal electrocardiogram can be observed in up to two thirds of patients.²⁴

Aortography

Historically, after the introduction of retrograde catheter aortography through the femoral artery in 1953 by Seldinger this technique became the diagnostic method of choice for acute dissection of the aorta.^{121,122} Diagnosis of aortic dissection relies on the detection of direct or indirect angiographic signs. Direct signs include evidence of a double lumen or an intimal flap; indirect signs are suggestive of acute dissection and include compression of the true lumen by the false lumen, thickening of the aortic

wall, aortic regurgitation, ulcer-like projections in the aortic wall, and abnormal position of the guide wire or catheter in the aorta.^{115,123} Biplane angiographic imaging of the thoracic aorta is mandatory because single-plane aortography can easily miss the diagnosis. The reported sensitivity and specificity of aortography in the evaluation of aortic dissection range between 80% and 90% and 85% and 95%, respectively.^{43,115} An aortic root injection can also detect coexistent coronary artery disease. In emergency situations, selective coronary angiography is not recommended unless the patient has undergone previous coronary bypass grafting or has a compelling clinical history suggesting severe coronary artery disease, because it delays institution of definitive treatment and can be hazardous. Aortography is an invasive technique and requires the use of iodinated contrast agents, which is another reason that catheter aortography is only of historical interest today. Aortography can be time consuming and is not an innocuous technique; moreover, concerns have been raised about the risk of iatrogenic proximal propagation or perforation of the dissection during manipulation of a guide wire or catheter within the aorta.¹²⁴

Computed Tomography

Harris and associates¹²⁵ were the first to report on the use of CT scanning in the diagnosis of aortic dissection in 1979. CT scanning is noninvasive, easy, and rapid to perform and can usually be performed without delay in emergency situations because a CT scanner is available near the emergency department in almost all hospitals, large or small. Because of major technological advances, acquisition of a large number of thin-slice images within seconds during one breath hold is now possible to create a CT angiogram (CTA). The newer dual-energy multi-detector CT machines substantially also reduce the amount of radiation required. Currently we use a second-generation dual-source scanner with two 128-slice detector systems, 270-ms gantry rotation time, and 75-ms temporal resolution (Siemens FLASH). A third-generation dual-source technology scanner is being installed soon. Furthermore, computer technology allows for complex reconstruction of high-quality CTA two-dimensional data, creating three-dimensional images or four-dimensional "cine" reconstructed video clips. The definitive diagnosis of aortic dissection requires the identification of blood flow in two distinct lumens separated by an intimal flap¹¹⁵; ancillary findings include compression of the true lumen by the false lumen, displaced intimal calcification, thrombosed false lumen or IMH, and ulcer-like projection of contrast material within the aortic wall consistent with a penetrating aortic ulcer.¹²⁶ A CTA is useful for accurate measurement of the aortic lumen diameters, and it can detect pericardial and pleural effusions; it also provides information about extent of dissection, arch involvement, and perfusion status of all major aortic branches. ECG-gated CTA can also image the coronary arteries adequately if the heart rate is not too high. The CT scan can also rule out other causes of acute chest pain. In the evaluation of patients with suspected aortic dissection, contrast-enhanced CTA has a

sensitivity of 82% to 100% and a specificity of 90% to 100%.[†] Disadvantages (beside the requirement for intravenous administration of contrast and use of ionizing radiation) of CT include the occasional inability to localize the primary intimal tear accurately, not being able to determine the severity of aortic regurgitation, and occasional poor visualization of rapidly moving flaps in an acutely dissected aorta because of relatively slow temporal resolution or motion artifacts, which has been minimized with the advent of ECG-gated thin-slice three-dimensional CTA.

Magnetic Resonance Imaging

The initial description of the use of MRI in the diagnosis of acute aortic dissection was made in 1983. MRI also is noninvasive; unlike aortography and CT scanning, MRI does not require the mandatory use of iodinated contrast even though magnetic resonance angiography (MRA) uses intravenous administration of gadolinium. MRI relies on the hydrogen ion concentration of blood and tissues to generate images.¹¹⁹ MRI can produce high-quality images of the aorta in the transverse, coronal, sagittal, and oblique projections, allowing excellent delineation of the entire aorta, reasonably accurate diameter measurement, and excellent assessment of associated pathoanatomic features (e.g., extent, localization of the primary intimal tear, branch artery involvement, and the presence of a pericardial effusion). Dynamic imaging with ECG-gated sequences and cine MRI modes can provide information about severity of aortic valve regurgitation and flow timing and direction in the aortic false and true lumens.^{115,117} In nonemergency situations, phase-contrast MRI has the unique capability to depict time-resolved three-dimensional blood aortic flow patterns as four-dimensional cine video clips. As with CT scanning, the criterion for the diagnosis of acute aortic dissection with MRI is the identification of two lumens with blood flow separated by an intimal flap. Similarly, identification of ancillary findings, as described before for CT imaging, is suggestive but not diagnostic of dissection.¹¹⁵ Several studies have shown that MRI is associated with sensitivity and specificity rates in the range of 95% to 100%.[‡] Immediate availability of MRA in urgent circumstances is not always present; another shortcoming of MRI is that it cannot be performed safely in patients with implanted pacemakers, defibrillators, or other ferrous metallic devices.¹³⁰ In the context of acute aortic dissection, MRI has many other limitations because of the relatively long time necessary for image acquisition and the inability to monitor and to treat severely ill, hemodynamically unstable patients while they are in the magnet. These practical factors make MRI not the first choice in patients with acute aortic dissection.

Echocardiography

Echocardiography is an attractive technique for the evaluation of patients with suspected aortic dissection because

[†]References 43, 44, 49, 115-117, 119, 126-129.

[‡]References 43, 44, 49, 115, 117, 119, 127-129.

it is ubiquitous, noninvasive, and easily performed at the bedside, and it does not necessitate the use of contrast material.^{115,117} Initially, only M-mode transthoracic echocardiography was available, but the introduction of two-dimensional echocardiography, color flow Doppler mapping, and now real-time three-dimensional echocardiography greatly improved visualization of the heart and the ascending aorta and permitted accurate assessment of valvular abnormalities and ascending aortic flow patterns.^{42,114,131,132} Transthoracic echocardiography only has a limited role because of suboptimal accuracy compared to other modern imaging modalities.^{117,127,133} The development of TEE overcame most of the technical limitations of transthoracic echocardiography in the evaluation of aortic dissection. High-resolution imaging of the heart and the thoracic aorta is possible with TEE because of the proximity of the esophagus to the aorta and heart. In addition, TEE provides information about aortic valve function, flow characteristics within the true and false lumens, left ventricular size and systolic function, and other associated cardiac valvular problems. Furthermore, TEE can also image the main left and right coronary arteries to rule out proximal coronary disease or involvement by the dissection. A limitation of TEE with the use of first-generation monoplane probes was limited visualization of the distal portion of the ascending aorta and the proximal arch because of the interposition of the trachea and left bronchus¹¹⁶; this limitation is now minimal with the use of multiplane or phased-array TEE probes. TEE can be performed in the emergency department, cardiac care unit, intensive care unit, or operating room with light sedation and topical anesthesia. Ideally, TEE should be performed after a fasting period of 1 hour or more to minimize the risk of aspiration, but in emergency situations this is not usually possible in the emergency diagnosis of acute aortic dissection. Close monitoring of vital signs is important during TEE. Contraindications to TEE include known esophageal disease (e.g., stricture, varices) and possibly severe coagulopathy.¹¹⁷ In the evaluation of patients with suspected aortic dissection, the most important diagnostic finding is the identification and location of an intimal flap, ideally seen in more than one view, undulating independently from the motion of the aortic wall or other cardiac structures.^{115,116,127,132,134} Visualization of different flow patterns in the true and false lumens and extrinsic compression in cases of false lumen thrombosis are other findings that suggest dissection or one of its variants, such as IMH or penetrating atherosclerotic ulcer with or without IMH.^{135,136} TEE for assessment of suspected aortic dissection has a sensitivity rate of 97% to 100% and a specificity rate of 68% to 98%.[§] False-positive test results, accounting for the lower specificity, were usually due to reverberation artifacts from surrounding cardiac structures or the aortic wall itself, producing echo images that were misinterpreted as an intimal flap in the ascending aorta.^{115,127} M-mode echocardiography can distinguish between a genuine intimal flap in the ascending aorta and reverberation artifact.¹³⁴ The main limitations of TEE

involve operator experience to interpret the findings accurately and the inability to assess branch vessel involvement (other than the coronary arteries) and extent of the dissection below the celiac axis level.

DIAGNOSTIC STRATEGY AT STANFORD UNIVERSITY AND SPECIAL DIAGNOSTIC CONSIDERATIONS

Stanford Diagnostic Strategy

Transesophageal echocardiography is currently the initial diagnostic procedure of choice for patients with suspected acute type A dissection because of its accuracy, safety, rapidity, and convenience. Patients with clear-cut TEE diagnostic findings are taken directly to the operating room for repair, whereas patients with inconclusive TEE findings require additional diagnostic studies (CTA or possibly MRA). Most patients transferred from outlying hospitals with suspected dissection have usually already undergone a contrast-enhanced CT scan and are taken directly from the helipad to the operating room, where the diagnosis is confirmed with TEE. In patients with symptoms of malperfusion or branch artery compromise, thin-slice gated CT angiography is the preferred diagnostic modality to evaluate both ascending aortic involvement and perfusion of major aortic branches in the chest and the abdomen. If malperfusion persists after proximal aortic repair, another emergency CT scan is performed immediately postoperatively to delineate the mechanism of persistent branch vessel compromise, which will guide appropriate endovascular catheter interventions to restore satisfactory distal perfusion.^{41,93,110} On the other hand, CTA or MRA is the best modality today to plan surgical intervention in patients with chronic type A dissection as well as to follow the aorta postoperatively. We prefer CTA preoperatively because it provides more detailed anatomic information for operative planning, but we use MRA liberally for serial surveillance follow-up scanning to minimize cumulative radiation exposure.^{49,99}

Intramural Hematoma

Criteria for the diagnosis of IMH involving the ascending aorta are displaced intimal calcification, a crescent-shaped nonopacified area along the aortic wall of more than 5 mm thickness, increased aortic wall diameter, and no evidence of aortic intimal disruption or flap.^{135,139} TEE, CTA, and MRA can detect IMH accurately and are capable of assessing progression or regression of the process during follow-up.¹⁴⁰ In this setting, MRI methods can estimate the age of the hematoma on the basis of the degradation of hemoglobin into methemoglobin after the acute event, resulting in high-intensity signals within the aortic wall on both T1- and T2-weighted images.²⁸

Coronary Angiography

The need for a selective coronary angiogram before surgical repair of patients with acute aortic dissection is

[§]References 43, 44, 49, 99, 115-117, 119, 127-129, 134, 137, 138.

vanishingly rare today and confined solely to special circumstances. The incidence of clinically important coronary artery disease (at least one stenosis $\geq 50\%$ or left main stenosis $\geq 75\%$ diameter reduction) in patients with acute type A dissection is between 10% and 35%.^{141,142} Ideally, patients in stable condition with an acute type A aortic dissection and a history of chronic angina, myocardial infarction, ischemic heart disease, or coronary artery bypass grafting should undergo coronary angiography preoperatively.¹⁴²⁻¹⁴⁴ On the other hand, coronary angiography should not be performed in patients who are unstable, which is frequently the case.⁴⁴ The drawbacks of coronary angiography include the obligate delay, technical difficulties, risk, and potential for false-positive findings. The Cleveland Clinic group reported that preoperative coronary angiography before emergency aortic surgery did not reduce perioperative mortality and did not affect the proportion of patients requiring coronary artery bypass grafting at the time of ascending aortic repair because 74% of coronary bypass grafts were performed for coronary dissection and not intrinsic coronary artery disease.¹⁴⁴ An earlier study from the Brigham and Women's Hospital by Rizzo and colleagues¹⁴⁵ indicated that coronary angiography was a surrogate for preoperative delay, which actually increased operative risk.

Biomarkers

The development of a reliable biomarker for the diagnosis of acute aortic dissection, in addition to imaging modalities, would help in the early identification of acute aortic syndromes in patients presenting with acute chest pain. Several such biomarkers have been investigated, such as D-dimer, circulating smooth muscle myosin heavy chain protein, soluble elastin fragments, calponin, and C-reactive protein.^{44,146-149} However, there currently is no rapid and reliable biomarker available that has been validated to confirm or to rule out the diagnosis of acute aortic dissection and its variants. More research in this arena is ongoing.

MANAGEMENT

Acute Type A Dissection

The aim of therapy in patients with acute aortic dissection is to prevent death and irreversible end-organ damage. A high clinical index of suspicion is mandatory in patients with suggestive signs and symptoms, followed by prompt confirmation of the diagnosis to determine the optimal management strategy. All patients with acute type A aortic dissections should be considered for emergency surgical repair of the ascending aorta to prevent life-threatening complications such as aortic rupture or tamponade.[¶] Exceptions to early operative intervention in patients with acute type A dissection are few, including those with an irreversible major stroke or deep coma,^{10,17,99,111} those with advanced, debilitating systemic

diseases that limit life expectancy or preclude meaningful rehabilitation, and perhaps those older than 80 years who have multiple major complications.¹⁵¹ These relative contraindications, however, have been challenged by some authors.¹⁵²⁻¹⁵⁵ For example, according to recent IRAD reports, patients with major brain injury or mesenteric malperfusion should not be denied early surgical intervention because their early and long-term prognosis is significantly improved compared with medical therapy only,^{111,155} because a majority of patients with stroke may experience partial or complete neurologic recovery after graft replacement of the ascending aorta. Individuals with paraplegia should also not necessarily be denied emergency operation; however, the chance of recovery of spinal cord function is almost zero. In our opinion, surgical repair of the ascending aorta should precede percutaneous vascular interventions addressing peripheral arterial complications of the dissection because "proximal" or "central" aortic repair will usually obviate the need for such distal revascularization procedures.^{102,156} In the Stanford experience focusing on aortic dissection associated with peripheral vascular complications, additional procedures after thoracic aortic repair were necessary in less than 10% of patients.¹⁰² Over the last 15 years, an alternative strategy has been advocated by the University of Michigan group that relies on initial percutaneous catheter interventions (flap fenestration, true lumen bare metal stenting) to restore end-organ perfusion with delayed repair of the ascending aorta after resolution of the malperfusion syndrome.^{157,158} This approach is attractive in that it allows immediate reperfusion and stabilizes the patient, and planned operative repair of the ascending aorta can be performed under better circumstances. In addition, if the end-organ ischemia or infarction has already become irreversible at the time of the catheter intervention, these complications are usually fatal, precluding attempting ascending aortic repair. Conversely, according to the limited data available so far, up to 15% of patients treated according to this alternative approach may die of aortic rupture during the stabilization period.

In most centers in North America and Europe, including Stanford, patients with acute type A IMH are managed identically to those with an acute type A aortic dissection because of the high complication risk that patients with acute type A IMH face.[¶] The rationale behind this approach is to prevent aortic rupture and cardiac tamponade as well as to avoid the rapid evolution of IMH into a classic full-blown dissection.^{**} This approach has been challenged by some, particularly in Korea, where intensive medical therapy is advocated for certain patients with uncomplicated acute type A IMH.¹⁵⁹⁻¹⁶¹ If a patient with acute type A IMH is treated medically, frequent serial imaging studies are mandatory because these patients can progress to overt dissection or aortic rupture within a short time; indeed, most ultimately require surgical intervention within 1 to 2 months.

As soon as the diagnosis of acute type A aortic dissection is suspected, comprehensive monitoring of neurologic status, arterial blood pressure, electrocardiogram,

[¶]References 14, 16, 17, 20, 23, 24, 35, 38, 40, 42-44, 49, 83, 99, 146, 150.

[¶]References 26, 28, 43, 44, 49, 95, 99.

^{**}References 26, 28, 30, 95, 135, 140.

urine output, and peripheral pulses is initiated. An arterial line, a central venous catheter, and a urinary catheter should be inserted. Intensive anti-impulse or negative inotropic therapy (lowering mean and diastolic arterial pressure and, more important, aortic dP/dt) is an integral part of the surgical management of patients with acute type A dissection before and after surgical repair to minimize propagation of the dissection, to decrease the risk of aortic rupture, and to control pain.¹² Intravenous anti-hypertensive and negative inotropic therapy should be started emergently, as soon as acute aortic dissection is suggested, using a beta blocker (e.g., intravenous esmolol, labetalol) initially or, if required, adding a short-acting arteriolar vasodilator, such as sodium nitropruside.^{17,43,44,49,162} Calcium channel antagonists can be used if contraindications to beta blockade exist. Hemodynamic instability suggests free aortic rupture, intrapericardial rupture with tamponade, or acute left ventricular failure secondary to severe aortic valve regurgitation or coronary compromise. In patients with severe hypotension and evidence of tamponade, pericardiocentesis should be attempted to resuscitate the patient only if immediate surgical intervention is not practical, with the goal of aspirating only enough fluid to allow the patient's blood pressure to rise to the lowest acceptable level to minimize the risk of frank aortic rupture (which can occur if the tamponade is completely relieved, causing arterial blood pressure to increase dramatically to high levels).¹⁰³

Surgical Principles

The primary goal of surgical treatment of patients with acute type A dissection is to replace the ascending aorta and proximal arch to prevent aortic rupture or proximal extension of the process with resultant tamponade. The primary intimal tear should be completely resected if it is located in the ascending aorta or the arch. The dissected aortic layers are reconstituted proximally and distally with fine continuous sutures (5-0 Prolene on C1 needle) with or without reinforcement to obliterate the false lumen. Aortic blood flow is redirected into the true aortic lumen distally, increasing the likelihood of reperfusion of aortic branches previously compromised by static or dynamic obstruction. When aortic valve regurgitation is present, aortic valve competence is achieved by reconstruction of the sinuses of Valsalva and aortic root with resuspension of the commissures, which is possible in many cases.^{99,104,163} If one or more of the sinuses of Valsalva is severely damaged by the dissection process, the patient has Marfan syndrome or other connective tissue disorder, a large root aneurysm is present, the patient has severe annuloaortic ectasia, or the valve needs to be replaced for other reasons (e.g., severe aortic stenosis), then complete aortic root replacement with reimplantation of the coronary ostia is indicated by use of either a composite valve graft (CVG) or a valve-sparing aortic root replacement technique, as advocated by Yacoub and David.¹⁶⁴⁻¹⁶⁶ In most cases, the noncoronary sinus of Valsalva is the most severely traumatized and can be treacherous to reconstruct satisfactorily; replacement of just the noncoronary sinus and the tubular ascending aorta (a "uni-Yacoub" procedure) is a simple approach that works

well in these circumstances. Valve-sparing aortic root replacement using David's reimplantation method might be the ideal technique in the setting of acute aortic dissection in young patients with normal valve leaflets, resulting in complete removal of all diseased tissue, less bleeding, and low incidence of need for late reintervention for aortic root or aortic valve problems.¹⁶⁷ The older technique of separate aortic valve replacement and supra-coronary aortic graft replacement is not used frequently any longer in patients with acute type A aortic dissections, but it is appropriate in older patients in whom the sinuses can be salvaged but aortic valve competence is not achievable otherwise.

Technical Considerations

Satisfactory hemostasis remains one of the chief technical challenges surrounding surgical repair of acute type A aortic dissection because of the friable dissected aortic tissue and the coagulopathy that may be present preoperatively. In the past, inclusion-wrap CVG methods (Bentall procedure) and ringed intraluminal grafts were used in an attempt to minimize bleeding; however, these techniques were associated with high failure rates and late problems, including perigraft leakage and false aneurysm formation with the former technique and migration, erosion, and stenosis with the latter.^{168,169} Most surgical authorities now believe that replacement of the dissected aorta includes complete transection of the aorta both proximally and distally and use of full-thickness aorta-to-graft anastomoses to minimize the risks of late complications.¹⁷⁰⁻¹⁷² A precise anastomotic technique is critical; deep suture bites should be used, with a continuous 5-0 C1 or 4-0 BB ($\frac{3}{8}$ circle needles) polypropylene (Prolene, Ethicon, Somerville, NJ). The needle must be advanced carefully on its full curve through the aortic tissue paying particular attention to the needle follow-through to avoid needle hole tears, which can cause troublesome bleeding or anastomotic disruption. If the aortic tissue is highly friable, reinforcement of the dissected aortic layers can be facilitated by reapproximation of the dissection flap to the aortic wall with strips of autologous or bovine pericardium or Teflon felt. European surgeons in the 1980s pioneered the use of gelatin-resorcin-formalin (GRF; "French glue") biological glue to reapproximate the dissected aortic layers which strengthened the aortic tissue to facilitate anastomotic suturing.¹⁷³ Despite wide use and good early results in many centers around the world,¹⁷⁴ concerns soon arose about the potential toxicity of the formalin component of GRF glue; late aortic wall necrosis leading to false aneurysm formation or anastomotic dehiscence occurred.^{175,176} As an alternative to GRF glue, a tissue adhesive composed of purified bovine serum albumin and 10% glutaraldehyde is currently approved (BioGlue, CryoLife, Inc., Kennesaw, GA) in the United States and can be used if necessary. This surgical adhesive is easy to use, facilitates the aortic repair, and decreases blood loss,^{177,178} but it is important to apply BioGlue cautiously. Minimal amounts should be used (just a 2-mm-thick layer extending only 2 cm into the false lumen is recommended), the regions of the coronary ostia must be

avoided, and the adhesive should not be applied far downstream where it may inadvertently enter the true lumen through a flap fenestration. Long-term results after the use of BioGlue are not available, but it also can cause necrosis of the delicate aortic wall. We have seen many cases in which the use of a large amount of BioGlue during the acute type A dissection repair later resulted in false aneurysms of the thoracic aorta, graft dehiscence, and full-thickness aortic necrosis 1 to 3 years later. Technical problems seen in earlier years with stiff woven vascular grafts have been eliminated by the advent of soft-woven, double-velour Dacron grafts that are presealed with bovine collagen impregnation (WDV Hemashield, Maquet Corp., Sunnyvale, CA), which are now routinely used for thoracic aortic surgery.¹⁷⁹ Satisfactory woven vascular grafts presealed with other types of biological sealants (e.g., gelatin in the Terumo Vascutek GelWeave grafts; Vascutek Ltd., Renfrewshire, Scotland) are also now available. Prophylactic administration of coagulation components including small, graduated doses of NovaSeven is also practiced today.

During the past two decades, PHCA, now coupled with selective antegrade cerebral perfusion (SACP) using axillary or innominate artery CPB cannulation, has become routine and safe in patients with acute type A dissection.^{85,99,180,181} This allows careful inspection of the aortic arch and performance of an open distal aortic anastomosis replacing the bulk of the transverse arch. Careful inspection of the arch minimizes the possibility of leaving unrecognized intimal tears in the arch, which are present in up to 20% to 30% of patients^{22,182} and increase the risk of late distal aortic reoperation. Radical “hemiarach” replacement is preferred, sewing obliquely from the ligamentum arteriosum on the lesser curve of the arch to the innominate artery take-off on the greater curve, which eliminates as much dissected aorta as possible. Simply performing an oblique “open” anastomosis in the distal ascending aorta is not recommended. Careful construction of a sound, completely hemostatic distal anastomosis is technically easier in the absence of an aortic cross-clamp, which itself can also traumatize the fragile dissected aortic tissue and tear the intima. An earlier analysis of all acute type A dissection repairs performed with or without PHCA at Stanford using propensity score analysis methodology demonstrated that aortic repair with circulatory arrest was associated with comparable early complication and survival rates.¹⁸³ This lack of superiority favoring PHCA was explained by the fact that in cases in the early years of this experience, PHCA was usually resorted to in desperate circumstances (e.g., aortic disruption or uncontrollable bleeding after the initial repair without PHCA). Although the long-term survival and late distal aortic complications were not improved after the use of PHCA in this risk-adjusted analysis, all surgeons at Stanford use PHCA with SACP routinely today in these patients on the basis of the technical advantages and theoretical potential merit of PHCA associated with an open distal aortic anastomosis. Adjunctive and more aggressive treatment of the distal dissected descending thoracic aorta using a “frozen elephant trunk” (FET) graft has recently gained favor in some experienced centers, as described later.

Operative Technique

General anesthesia is induced intravenously. After intubation, anesthesia is maintained with a combination of inhalation agents and short-acting narcotics. An antifibrinolytic agent such as ϵ aminocaproic acid (Amicar) or tranexamic acid is used routinely to minimize fibrinolytic activity typically observed with CPB and PHCA.¹⁸⁴ Electrocardiography, arterial pulse oximetry, radial and femoral arterial pressure, central venous pressure, bladder (or nasopharyngeal) and tympanic membrane temperatures, and noninvasive near-infrared cerebral oximetry are monitored throughout the operation. TEE is used in all patients to assess the dissected aorta, flow patterns in both the true and false lumens (before, during, and after CPB), aortic valve competency, and left ventricular size and systolic function.

A midline sternotomy incision is used for repair of acute type A dissection. Simultaneous exposure of the right axillary artery is made for arterial CPB cannulation, which is used preferentially in patients with acute type A dissections to provide antegrade blood flow during CPB perfusion and cooling,^{49,99,185-187} and then SACP when PHCA is instituted; this technique is safe, is simple to perform, and avoids retrograde femoral arterial perfusion, which can lead to inadvertent false lumen pressurization and thoracoabdominal or cerebral malperfusion as well as cerebral embolization from debris in the abdominal or descending aorta. Subclavian arterial cannulation is performed with a short, 6- or 8-mm knitted double velour (Microvel Hemashield, Maquet Corp., Wayne, NJ) Dacron graft anastomosed end-to-side to the right axillary artery. If the artery is dissected, it is essential to sew the perfusion graft to the true lumen for safe CPB perfusion. A two-stage venous cannula is inserted into the right atrium through the appendage. The typical CPB circuit used for the surgical management of acute type A aortic dissection is illustrated in [Figure 70-6](#). CPB is established slowly with continuous TEE monitoring of the flow pattern within the ascending and descending aorta and arch to detect any evidence of distal malperfusion, which is suspected if the true lumen becomes small or obliterated. If this occurs, direct cannulation of the aortic true lumen in the arch using the Seldinger technique either with TEE guidance^{99,188-190} or by passing a longer arterial cannula through the left ventricular apex and across the aortic valve into the true lumen (as originally described by Wada and Kazui in the 1970s for mitral valve surgery through a left thoracotomy).^{99,191} One drawback of direct aortic or transapical LV arterial CPB cannulation is that additional steps are necessary to institute SACP when the pump is turned off to do the arch anastomosis; this might explain the high neurologic complication rates seen in Hannover and Essen, Germany, where the direct aortic cannulation technique was popularized. In emergency situations, starting with femoral CPB cannulation is acceptable followed by CPB perfusion from the ascending aortic graft or a side-branch. Alternatively, carotid artery cannulation has been described.¹⁹² A vent is inserted into the left ventricle through the right superior pulmonary vein or directly across the ventricular apex to prevent

FIGURE 70-6 ■ Schematic of the cardiopulmonary bypass circuit for repair of an acute type A aortic dissection with an open distal anastomosis during a period of hypothermic circulatory arrest and selective antegrade cerebral perfusion. Arterial cannulation is performed with a short 6-mm Dacron graft anastomosed end to side to the right axillary artery.

distention. Systemic cooling is initiated, avoiding gradients of more than 10°C between the patient and the arterial perfusate temperature, and continued for at least 30 minutes or until tympanic temperatures approaches 20°C ; bladder temperature is usually in the range of 25° to 28°C . It is important to monitor the tympanic membrane temperatures and cerebral oximetry during cooling and rewarming to detect inadequate or asymmetric cerebral CPB perfusion. If such perfusion occurs, the aorta is examined using TEE to determine why one of the arch branches is not being perfused adequately, and recannulation needs to be considered. In addition, preparations are made in advance to perfuse the left common carotid artery and/or left subclavian artery with balloon-tipped perfusion cannulae when SACP is instituted. During cooling, the aortic root and ascending aorta are carefully dissected away from the right and left atria, right ventricular outflow tract myocardium, pulmonary valve annulus, and main and right pulmonary arteries. The pericardial reflection (or "veil") covering the left main coronary artery, which extends anteriorly and leftward to the pulmonary annulus, must be divided following the right and main pulmonary arteries. The ascending aorta is not clamped during cooling except when unmanageable severe aortic valve insufficiency mandates aortic clamping to prevent left ventricular distention. Dexamethasone (8 to 12 mg) is administered before commencement of CPB to enhance cerebral and spinal cord

protection. Mannitol (0.3 to 0.4 g/kg) and furosemide (40 to 80 mg) are given when commencing CPB to minimize ischemic reperfusion injury (hydroxyl and superoxide free radical scavengers). The head is packed in ice. The field is flooded with CO_2 gas. After CPB flow is reduced to 10 mL/kg/min , the cross-clamp is removed, the aorta is opened, and SACP is begun slowly. After confirmation that CPB pump flow is entering the arch from the true lumen of the innominate artery, the innominate artery is clamped, and the back-bleeding down the left common carotid artery and then the left subclavian artery is inspected, indicating patency of the circle of Willis. If the back-bleeding is red and relatively brisk, these two arch branches are sequentially clamped. If the left common carotid artery or subclavian artery back-bleeding is visually judged to be inadequate (trickle back flow or dark blood returning) or asymmetric tympanic membrane temperatures or cerebral oximetry is detected, additional perfusion cannulas can be inserted directly into the left common carotid and/or subclavian arteries. Unilateral SACP is usually adequate in our experience, but it should be noted that Dr. Kazui's original SACP method involved perfusion of all three arch branches at a total flow rate of 10 mL/kg/min .¹¹¹ Intermittent retrograde cold blood cardioplegia and topical cooling (Daily Cooling Jacket, Daily Medical Products, Luke Medical, Inc., Plymouth, MN) are used for myocardial protection.

FIGURE 70-7 ■ **A**, An open distal anastomosis is always used to avoid intimal damage with a clamp and to allow inspection of the aortic arch. The aorta is transected immediately proximal to the innominate artery and distally toward the lesser curvature to the level of the left subclavian artery. An appropriately sized graft is beveled and anastomosed with 4-0 polypropylene suture. The Gripp method of rotating the beveled end of the graft 180 degrees such that the “toe” of the graft actually apposes the greater curve of the arch near the innominate artery is used, which tucks the completed graft into the natural curve of the arch and prevents excessive angulation of the graft. Most commonly, the false lumen is obliterated with the anastomotic suture line without reinforcing material. **B**, After aortic root reconstruction and resuspension of the valve commissures, the graft is anastomosed to the reconstructed proximal aortic cuff in an end-to-end fashion with a running 4-0 polypropylene suture.

The ascending aorta is opened to locate the primary intimal tear and to evaluate the aortic valve and sinuses, and then the arch and proximal descending thoracic aorta are inspected. The aortic segment containing the intimal tear is resected, and the aortic arch is trimmed circumferentially in an oblique fashion in preparation for extended hemiarch replacement. Reapproximation of the distal aortic layers is preferentially accomplished as part of the distal anastomotic suture line in the arch; if absolutely necessary, a small amount of tissue adhesive or BioGlue the dissected layers can be helpful. An end-to-end aortic anastomosis is then carried out with an appropriately sized and beveled woven, double velour Hemashield Dacron graft with a continuous 5-0 C1 or 4-0 BB polypropylene suture (Fig. 70-7A). We do not prefer to do so, but suturing two strips of pericardium or Teflon felt (one inside the false lumen and one externally) with a separate 4-0 BB polypropylene suture line to form a solid full-thickness distal aortic cuff can be done to reconstitute very friable aortic layers before the distal arch anastomosis. The counter-intuitive technique pioneered by Dr. Randall Gripp of rotating the beveled distal end of the graft 180 degrees such that the “toe” of the graft actually apposes the greater curve of the arch near the innominate artery is important and always is used, which tucks the completed graft tightly into the natural curve of the arch and prevents the lesser curve of the graft from being too long, which causes excessive

angulation of the graft rightward and anteriorly and kinking. When the arch anastomosis is completed, the left subclavian artery, left common carotid artery, and innominate artery clamps are sequentially removed with the patient placed in steep Trendelenburg position, and the arch and great vessels are de-aired using manual massage. CPB flow is resumed in an antegrade fashion using the original axillary artery cannula, and the arch graft is clamped. Flow in the descending aorta is quickly assessed with TEE to ensure that the true lumen has not become obliterated by a pressurized false lumen. After 10 minutes of cold systemic reperfusion, gradual rewarming of the patient to 35° C (bladder) is initiated.

The aortic root and valve are then evaluated and additional intimal tears are excised. If aortic root replacement is not necessary, the ascending aorta is transected immediately above the sinotubular junction. Valvular regurgitation secondary to commissural detachment can be corrected by resuspension of the tops of the commissures at the level of the sinotubular junction using pledgeted 5-0 polypropylene sutures at each commissure to approximate the dissected layers of the sinuses of Valsalva; this technique will result in aortic valve competence in 70% to 80% of patients.^{104,163,193} A second woven double velour graft of appropriate diameter is then anastomosed to the reconstructed proximal aortic cuff in an end-to-end fashion with a running 5-0 C1 or 4-0 BB polypropylene suture (see Fig. 70-7B). Finally, the two grafts are

shortened on reverse bevels such that the lesser curve side is much shorter, and a graft-to-graft anastomosis is constructed using 3-0 RB1 polypropylene. We use two separate grafts to avoid geometric distortion and torquing the friable aortic anastomoses. A needle vent is inserted in the graft for de-airing, and the cross-clamp is released. TEE rapidly confirms whether the aortic valve is competent, and the anastomoses are inspected. Short-axis TEE views of the aortic root confirm satisfactory main coronary artery perfusion. When the patient is adequately rewarmed, CPB is discontinued, and protamine sulfate is administered after all anastomoses are judged to be technically satisfactory with minimal bleeding. Platelets, fresh-frozen plasma, cryoprecipitate, or small fractionated doses of NovaSeven are administered if diffuse hemorrhage from needle holes, suture lines, and raw surfaces is evident after a normal activated clotting time is achieved. Coagulation abnormalities identified by rotational thromboelastography guides administration of specific coagulation components.¹⁹⁴

More Radical Management of the Aortic Root

Patients with dissection-related destruction of the aortic root, individuals with Marfan syndrome or other connective tissue disorder (including bicuspid aortic valve), and those with markedly dilated sinuses of Valsalva or annuloaortic ectasia should undergo CVG root replacement or valve-sparing aortic root replacement using the David reimplantation method with complete excision of the sinuses of Valsalva (see [Chapter 67](#)), rather than resuspension of the aortic valve and preservation of the sinuses. A conservative approach limited to replacement of just the tubular segment of the ascending aorta in these cases is associated with suboptimal long-term results and a high likelihood of subsequent aortic or aortic valve problems requiring reoperation.^{104,171,195} Complete aortic root replacement with a CVG has become more popular over the past decade since it is reliable and no residual dissected or weak sinus tissue remains, but does expose the patient to the consequent cumulative morbidity associated with valve replacement.

Since the noncoronary sinus of Valsalva usually is the one most severely involved by the dissection process, an alternative technique is a “uni-Yacoub” procedure where the entire noncoronary sinus is replaced using a single proximal “U-shaped” tongue fashioned from the aortic graft suturing close to the hinge of the aortic cusp with a fine (5-0 C1) polypropylene suture. Occasionally, even a “bi-Yacoub” procedure—replacing the noncoronary and the right sinuses of Valsalva with right coronary artery reimplantation—can be useful if both sinuses are destroyed. If the aortic valve is markedly abnormal or cannot be repaired in a durable fashion, separate valve and supracoronary aortic graft replacement is a reasonable alternative in certain patients if it is performed according to the tenets of the original Wheat-Shumway-Groves procedure, in which minimal sinus tissue remains above the annulus except for tongues surrounding the left and right coronary ostia.¹⁹⁵ Direct extension of the dissection into the coronary ostia is not common (more

often in the right coronary artery), and can be challenging to correct.¹⁰⁵ The flap in the sinus running close to the proximal main coronary ostium can usually be glued together in the proximal aortic reconstruction. On occasion, the safest solution is complete CVG root replacement with reimplantation of reconstituted coronary artery ostia as full-thickness Carrel patches (or buttons) into the graft, either directly or using a short interposition saphenous vein graft as introduced by Zubiarte and Kay.¹⁹⁶ Alternative techniques include the Cabrol-II moustache coronary reconstruction with a small synthetic graft¹⁹⁷ and, in exceptional circumstances, suture ligation of the coronary and bypass grafting.^{105,198}

Management of the Aortic Arch

In up to approximately 30% of patients, the primary intimal tear is found in the aortic arch, which has historically been associated with a poorer prognosis.^{22,84,85,182} Most tears are located on the lesser curve of the arch under the innominate artery, permitting complete resection of the tear using the extended arch technique with a single sigmoid-shaped suture line running from the ligamentum on the lesser curve to the innominate artery on the greater curve. In cases in which the primary intimal tear is located more distally in the arch, on the greater curve in proximity to branch vessels, or when arch rupture or a preexistent arch aneurysm is encountered, total arch replacement is required, but is associated with higher perioperative mortality and morbidity, especially in older and critically ill patients.^{84,85,199,200} With a primary tear located in the arch, failure to include the arch in the repair increases the probability of requiring subsequent distal aortic reoperation and reduces long-term survival.⁸⁵ Improvements in surgical techniques and brain protection during PHCA and SACP²⁰¹ have made concomitant total arch replacement a reasonable and safe option in selected patients when necessary.^{99,202} A recent report from the German Registry for Acute Aortic Dissection Type A (GERAADA) evaluating cerebral protection methods in 1558 patients operated between 2006 and 2009 found that the operative mortality and the incidence of permanent neurologic dysfunction were lower using SACP compared with PHCA only, especially for longer circulatory arrest periods that are required for complex arch reconstructions.²⁰¹ In these circumstances, total arch replacement is performed using a distal elephant trunk graft technique, which can be a simple downstream FET stent-graft in the aortic true lumen tacked around the left subclavian artery takeoff, as popularized by Pochettino and colleagues^{203,204} and Roselli and colleagues²⁰⁵ (discussed later), or complete arch replacement. Instead of using the original 1982 Borst arch replacement with elephant trunk graft technique, in which the three arch branches were reimplanted en bloc as a single island (see [Chapter 68](#)),²⁰⁶ a multibranched arch graft is used when complete arch replacement is necessary.^{207,208}

Distal Frozen Elephant Trunk Graft

The open arch replacement approach enables one to add a downstream surgical elephant trunk graft or a FET

stent-graft in the true lumen of the descending aorta, which theoretically will reduce the rate of late false lumen aneurysmal degeneration. Pochettino and Roselli in the United States, Karck, Jakob, Haverich, Mestres, and Di Bartolomeo in Europe, Kazui and others in Japan, and Sun in China have championed this approach,^{203,205,209-211} which can be performed by modifying a commercial thoracic aortic stent-graft or using a specially designed commercial device. This downstream adjunctive procedure, however, does increase the chance of spinal cord injury, and may incrementally increase operative mortality risk. In Europe, this is being accomplished using commercial hybrid integrated stent-graft devices such as the Terumo Vascutek Thoraflex multi-branch graft (Vascutek Ltd.) and the Jotec "E-vita open" system (Jotec, Hechingen, Germany), which are specially designed integrated commercial devices that incorporate the arch graft segment and the distal stent-graft.²¹² In China, the Cronus FET (MicroPort Medical, Shanghai, China) along with a standard four-branch arch graft have been used extensively by Sun and his group in Beijing.²¹³ While this approach is gaining popularity, what is not known is which patients are at highest risk for subsequent downstream aortic complications who theoretically would benefit most from this more aggressive adjunctive procedure during the initial operation.²¹⁴ Results of future investigations using these devices will help to define who will benefit from this aggressive downstream surgical approach. Ideally, a multicenter, prospective randomized controlled trial will be launched to investigate this question, but securing adequate funding for such a trial has been unsuccessful.

Special Situations

Primary Intimal Tear in the Descending Thoracic Aorta (Retro-A Dissection). In 5% to 10% of cases, acute type A aortic dissection is due to retrograde extension of the dissecting process from a primary intimal tear located in the descending thoracic aorta, a situation that Reul and Cooley in 1975 termed a *DeBakey type III-D dissection*.^{17,21} We prefer the simpler term *retro-A dissection*, as introduced by Lansman, Griepp, and the Mount Sinai group.²² Furthermore, the incidence of retro-A dissections has increased considerably as a devastating complication of endovascular descending aortic stent-grafting (TEVAR). Patients with this subtype of acute type A dissection were thought to have a poor prognosis because of intraoperative complications,^{17,22} including hemorrhage from the distal aortic anastomosis, or rupture of the descending aortic false lumen during or after ascending aortic replacement.^{22,215} To prevent these complications, single-stage resection of the primary intimal tear in the descending aorta with replacement of the ascending aorta and entire arch through a median sternotomy or left thoracosternotomy incision has been proposed in carefully selected patients with a patent false lumen in the ascending aorta, aortic regurgitation, cardiac tamponade, or marked dilation of the ascending aorta.²¹⁵

In patients in whom the false lumen of the ascending aorta has thrombosed and no dilation of the ascending aorta or aortic regurgitation is present, continuing medical therapy may be reasonable^{216,217}; however, our

philosophy usually calls for more aggressive surgical treatment, meaning at least graft replacement of the ascending aorta and partial or total arch replacement in younger individuals if they are suitable operative candidates. More recently, TEVAR has been applied in patients with a natural retro-A dissection with favorable midterm results^{218,219} as an isolated procedure designed to cover the primary intimal tear in the descending aorta hoping this will accelerate thrombosis of the false lumen in the arch and ascending aorta, or in conjunction with extended surgical replacement of the ascending aorta and arch.²¹¹ Arch replacement plus a distal frozen elephant trunk approach, described above, can also be an option in these circumstances.^{203-205,209-215}

Type A Aortic Dissection and Coarctation. Acute aortic dissection in the presence of an untreated aortic coarctation is a rare problem, with few reported cases in adults.^{60,62} Simultaneous repair through a median sternotomy incision is advocated by most authors if the patient is young. Retrograde femoral arterial CPB perfusion of the brain through the coarctation is problematic in this situation, with resultant cerebral hypoperfusion; this potential problem is avoided with right axillary artery CPB cannulation coupled with simultaneous femoral CPB perfusion if the obstruction at the coarctation is severe. In addition to standard ascending aortic and arch dissection repair, the coarctation can be treated with a bare metal stent, TEVAR, or an extra-anatomic bypass from the ascending aortic graft to the distal descending aorta, through the posterior pericardium.^{61,62}

Postoperative Malperfusion. Diligent surveillance postoperatively is needed to detect persistent or new malperfusion before irreversible infarction of important end organs occurs. Today, most if not all of the persistent or new malperfusion syndromes after surgical repair of aortic dissection can be managed with endovascular techniques, including stent-graft implantation, balloon flap fenestration, and direct stenting of the true lumen of compromised branches.^{41,99} Specific management of branch vessel malperfusion is discussed in more detail in [Chapters 71](#) and [72](#).

Chronic Type A Dissections

Indications for Operative Intervention

Operation for patients with chronic type A dissection is indicated if symptoms occur or if progressive aortic enlargement is present, including symptoms of congestive heart failure or evidence of left ventricular dysfunction or dilation because of severe aortic valvular regurgitation. In asymptomatic patients, surgical intervention is generally recommended when the diameter of the ascending aorta is greater than 55 to 60 mm (50 mm in patients with Marfan syndrome) or if the documented rate of expansion is greater than 5 to 10 mm during 1 year.^{49,112,220,221} Dissected thoracic aortas rupture at a smaller size than do degenerative or atherosclerotic thoracic aortic aneurysms.²²² Seasoned surgical judgment is important on an individualized basis. The expected

benefits of graft replacement of the aorta in asymptomatic patients must be weighed against the operative risk, taking into account the frequent medical comorbidities these patients have that increase surgical risk or otherwise limit life expectancy; these risk factors, paradoxically, are also the same variables that portend a higher risk of aortic rupture (e.g., Marfan syndrome, other connective tissue disorders, uncontrolled hypertension, increasing age, and chronic obstructive pulmonary disease).^{220,221} Expansion of the size of the false lumen in the distal aorta (usually the proximal descending thoracic aorta) after successful proximal aortic repair or local complications of a previous operation (e.g., aortic root aneurysm, anastomotic false aneurysm, worsening aortic regurgitation) are also indications for operation in patients with a chronic type A aortic dissection.^{112,223}

Surgical Technique

More extensive resection and more complex aortic reconstruction are generally necessary in patients with chronic type A dissections compared to their acute type A counterparts. Preservation of the aortic valve and sinuses of Valsalva is usually not achievable in these circumstances; if it is possible, the repair may not be durable. Aortic root replacement using a CVG is required in most circumstances. In highly select young patients, the Tirone David reimplantation technique valve-sparing aortic root replacement may be feasible to avoid long-term anticoagulation, but only if minimal scarring is present or if there is not too much deformity and scar around the synthetic material used at a previous operation (see [Chapter 67](#)).^{164,166} Since large false lumen aneurysmal degeneration frequently exists in the aortic arch and descending thoracic aorta in the setting of chronic type A dissection, total arch replacement with an elephant trunk graft after flap septectomy in the descending thoracic aorta is often necessary to facilitate staged subsequent replacement of the descending thoracic aorta; alternatively, if there are no or few large fenestrations in the dissection flap in the descending aorta, then a stent-graft (TEVAR or FET) deployed antegrade carefully in the true lumen of the descending aorta can result in subsequent false lumen thrombosis proximally, which hopefully progresses caudad over time (see [Chapters 68 and 72](#)).^{112,206,223-225} Alternatively, a single-stage “arch first” approach using PHCA (with antegrade SACP via the right axillary artery) for patients with chronic type A dissections as pioneered by Kouchoukos using a bilateral anterior thoracotomy or clamshell incision provides excellent long-term durability with reasonable operative mortality and morbidity risks.²²⁶ The most common complication is respiratory insufficiency requiring temporary tracheostomy. This simultaneous approach involves replacement of the transverse arch first under deep hypothermic circulatory arrest to minimize cerebral ischemic time, followed by descending thoracic or thoracoabdominal aortic replacement.²²⁶

In contrast to patients with acute dissection, perfusion of downstream vital organs may depend solely on a patent false lumen in the chronic phase of dissection; hence, maintaining antegrade flow in both the true and the false

lumens can be vital to avoid iatrogenic malperfusion after aortic repair. To achieve this goal, flap septectomy with or without distal flap fenestration is performed to allow blood flow to perfuse both the distal aortic true and false lumens downstream with a short dangling elephant trunk graft in the distal “common chamber” of the descending thoracic aorta or supraceliac abdominal aorta.

RESULTS

Early Survival

Contemporary reports have documented improved surgical outcome in patients with aortic dissection, with perioperative mortality rates decreasing from 30% to 60% in the 1960s to 5% to 25% in the last 2 decades.^{††} These lower early mortality rates were attributed to progressive advances in diagnosis and imaging; improved surgical methods, better myocardial protection, more sophisticated CPB techniques; improved perioperative management; and increased surgical experience. Other factors, such as patient referral patterns and patient selection bias, however, must also be considered when comparing retrospective results between various eras and between different institutions. It is sobering to note that the most recent IRAD 2014 report showed that the early mortality rate in surgically treated patients with acute type A dissection was greater than 20% between 1996 and 2013 in 1995 patients collected from 24 centers worldwide.²⁴⁰ At Stanford University between 1963 and 1992, the overall operative mortality rate was 26% in 174 consecutive patients undergoing surgical repair for acute type A aortic dissection, decreasing from 38% in the 1963-1976 period to 27% in the 1988-1992 period.¹⁰ In this 30-year experience, the independent determinants of early mortality were earlier operative year, older age, hypertension, preoperative cardiac tamponade, and renal dysfunction. More recently, the early mortality rate decreased to 17% in a series of 151 patients presenting with an acute type A aortic dissection operated on between 1993 and 1999 (see [Fig. 70-7](#)),¹⁸³ consonant with other large contemporary series of surgical treatment of patients with acute type A dissections.^{††} In the entire cohort of Stanford patients, the independent risk factors for early death were again earlier operative year, older age, preoperative tamponade, and renal dysfunction. Overall, it appears that patient-specific factors and not treatment strategies (e.g., the use of PHCA) were the main determinants of adverse outcome. The only potentially modifiable factors, moreover, were cardiac tamponade and renal dysfunction, which might theoretically be lower if the diagnosis is made earlier. Interestingly, site of intimal tear, pulmonary disease, and arterial hypertension, which were significant in earlier analyses,¹⁵⁰ did not increase the likelihood of death in the later years of this 37-year series.

These observations parallel findings reported in other contemporary reports from centers with special expertise

in thoracic aortic surgery. According to older analyses by Crawford and colleagues, earlier operative date, severe symptoms, presence of coronary artery disease, diabetes mellitus, reoperation for bleeding, postoperative stroke, and cardiac complications were independent risk factors for early death after surgical treatment of type A dissection.^{84,234} In the Cleveland Clinic experience with 135 acute and 73 chronic type A dissections, independent predictors of early mortality were earlier operative year, hemodynamic instability, not using PHCA, longer PHCA time, need for composite valve graft for aortic root replacement, and concomitant coronary artery bypass grafting.²³³ Increasing age, hemodynamic compromise, and absence of hypertension were identified as risk factors for hospital death in the Mount Sinai experience⁸²; renal or mesenteric ischemia and preoperative shock predicted early deaths in Kazui's experience in Japan.²²⁹ In a retrospective analysis of a U.S. national administrative database (nationwide inpatient sample [NIS]) including 3013 patients undergoing surgical repair of acute type A aortic dissection between 1995 and 2003 in the United States, the mortality rate was 26% and the only independent determinants of early death were increasing age and operation in a nonacademic hospital.²³⁷ Another analysis of outcomes in 5184 patients operated for acute aortic dissection from 2003 to 2008 in the U.S. NIS database observed an overall mortality rate of 21.6% (19.1% between 2005 and 2008) and found a strong inverse relationship between operative mortality and both surgeon and institutional volume, suggesting that repair of acute aortic dissection may display a volume-outcome relationship similar to what is seen in other cardiovascular surgical diseases.²³⁹ Among 526 patients in IRDA with acute type A dissection enrolled prospectively between 1996 and 2001, predictors of early death were previous aortic valve replacement, migrating chest pain, shock or tamponade at presentation, and preoperative peripheral malperfusion,²³⁶ again emphasizing the importance of patient-specific factors and dissection-related complications in terms of surgical risk.

Finally, perhaps all is not stagnant in this field. In 2014, a report from Duke University demonstrated that these sobering surgical results for acute type A aortic dissection can be improved if a dedicated multidisciplinary thoracic aortic team is implemented.²⁴¹ They compared their results over 5-year intervals before (1999-2005) and after (2005-2011) this team was established. In the earlier era, an average of nine acute type A repairs were performed each year by 11 different surgeons. After 2005, an average of 12 cases was done annually, but 97% of them were performed by two specially trained thoracic aortic surgeons. Operative mortality rate fell from 34% to 2.8%, and this translated directly into improved 4- to 5-year survival results. Using the IRAD predicted risk algorithm, the observed-to-expected 30-day mortality ratio fell from 1.26 to 0.15; although the more recent patient substrate was at somewhat lower risk, this is a tremendous achievement. Although an annual acute type A dissection volume of 9 to 12 cannot be considered to be a high-volume institution, one of the NIS studies revealed that only 15 NIS-participating institutions in the United States performed over 10 cases per year,

which is an astoundingly low number.²³⁷ Nonetheless, the accompanying editorial declared that ample opportunity clearly exists in the United States and presumably other countries around the world to improve outcomes if health policy regulators and payers enforce strict regionalization of thoracic aortic surgical services such that the vast majority of patients with all types of thoracic aortic disorders—including acute type A dissections—would be cared for in a small number of institutions with greater experience and special expertise.²⁴² The editorialist opined that in the United States only one thoracic surgical center would be necessary for every 5 to 10 million inhabitants, meaning only 32 or possibly 64 specialized institutions in the United States (out of approximately 1325 hospitals performing more than one thoracic aortic case per year between 1999 and 2010) would be reimbursed for thoracic aortic surgery cases to cover our population of 316 million.²⁴² This health policy process improvement step is long overdue.

On the other hand, early mortality risk after surgical treatment of patients with chronic type A dissection is generally lower than that for patients with acute dissections. In the 1995 summary of the Stanford 30-year experience, early mortality rate was 17% in 106 patients with chronic type A dissections and only 6% in the subgroup of patients with Marfan syndrome.¹⁰ In an analysis of 690 patients with aortic dissections during a 33-year period, Crawford and colleagues²³⁴ observed a 30-day mortality rate of 12% in patients with chronic type A dissections operated on before 1986 and only 8% in those operated on after 1986. Independent determinants of death were severity of symptoms, previous aortic surgery, concomitant coronary artery disease, use of intra-aortic balloon pump, cardiac complications, and postoperative stroke. Similarly, Sabik and associates²³³ from the Cleveland Clinic reported an early mortality rate of 11% in 73 patients with chronic type A dissections treated surgically. More recently, refinements in surgical techniques, including the use of the FET technique or the arch-first technique, have led to improvements in surgical outcomes with reported early mortality rates as low as 4%.^{112,223,226}

Late Survival

In DeBakey's seminal 1982 report on long-term results in 527 surgically treated patients with aortic dissection (type A or B, acute or chronic), the overall survival estimates were 57%, 32%, and 5%, after 5, 10, and 20 years, respectively.¹⁶ In patients with type A dissections, 29% of late deaths were attributed to complications related to rupture of the dissected aorta in a remote downstream location, emphasizing the long-term life-threatening nature of aortic dissection and the need for improved long-term imaging surveillance, prophylactic reoperation when indicated, and intensive medical follow-up care.

In the 30-year Stanford experience, the overall survival rates (including hospital deaths) for patients with acute type A dissections at 1, 5, 10, and 15 years were 67%, 55%, 37%, and 24%, respectively.¹⁰ For patients with chronic type A dissections, long-term survival estimates at these same times were, respectively, 76%, 65%, 45%,

FIGURE 70-8 ■ Operative mortality rates as a function of time for patients with acute type A dissection operated on between 1963 and 1999 at Stanford University and broken down according to treatment method. *Non-PHCA*, No circulatory arrest; *PHCA*, profound hypothermic circulatory arrest. (From Lai DT, Robbins RC, Mitchell RS, et al: Does profound hypothermic circulatory arrest improve survival in patients with acute type A aortic dissection? *Circulation* 106:1218-1228, 2002. Copyright 2002, American Heart Association.)

and 27%. For patients with acute type A dissections, the late survival estimate for discharged patients was 91%, 75%, 51%, and 32% at 1 year, 5 years, 10 years, and 15 years, respectively, compared with 93%, 79%, 54%, and 33% for those with chronic type A dissections. One third of the late deaths were cardiac related, but at least 15% of deaths were due to complications related to the downstream chronic aortic dissection. Multivariable analysis identified older age and previous cardiovascular operation to be significant risk factors for late death; interestingly, previous stroke, remote myocardial infarction, chronic renal dysfunction, and earlier operative date, which were independent predictors of adverse late outcome in the 1985 Stanford analysis,⁴⁰ no longer emerged as risk factors in the larger, more recent analysis. In the more recent report from Stanford of patients with surgically treated acute type A dissections, independent determinants of late death were increasing age, previous sternotomy, prior stroke, hypertension, liver disease, tamponade, arch involvement, and earlier year of operation; use of PHCA and resection of the intimal tear were not identified as significant predictors of late death.¹⁸³ Actuarial survival after surgical repair of acute and chronic type A aortic dissections in the patients operated on at Stanford University between 1963 and 2000 is shown in Figures 70-8 and 70-9.

In Crawford's 1990 report, survival at 1, 5, and 10 years in patients with proximal dissections (acute or chronic) was 78%, 63%, and 55%, respectively²³⁴; life expectancy was significantly worse in patients with acute dissections (67% for acute versus 81% for chronic at 1 year, and 51% versus 68% at 5 years). Independent predictors of late death in all patients included severity of symptoms, New York Heart Association (NYHA) functional class, distal extent of resection, unresected residual aneurysm, postoperative complications, and earlier year of operation. In his 1992 updated series focusing only on acute type A aortic dissections,⁸⁴ Crawford reported

FIGURE 70-9 ■ Actuarial survival after operative repair of acute type A aortic dissection in 323 consecutive patients operated on between 1963 and 2000 at Stanford University Medical Center.

survival estimates at 5, 10, and 20 years after surgical repair of 56%, 46%, and 30%, respectively. Determinants of mortality in this series were earlier year of operation, inclusion of the arch in the repair, NYHA functional class, diabetes, and concomitant coronary artery bypass grafting. In the Cleveland Clinic experience, long-term survival was comparable between those with acute and those with chronic type A dissections; older age, higher blood urea nitrogen concentration, aortic arch replacement, and earlier date of operation were incremental risk factors for late death.²³³

Recent, large single-center and multicenter clinical reports corroborate these results and show only modest improvement in the long-term prognosis after surgical repair of acute type A aortic dissections during the last

two decades. In their extensive experience with 315 patients operated on during a period of 27 years, Tan and colleagues from the Netherlands reported survival (of discharged patients only) at 1 year, 10 years, and 20 years of 96%, 68%, and 39%, respectively. In their series, advancing age and renal failure were the only predictors of late death.^{242a} In the Mt. Sinai analysis of their contemporary cohort of patients operated on with a standardized surgical approach, Griep and colleagues reported survival estimates at 1, 5, and 10 years of 91%, 78%, and 66%, respectively, for hospital survivors.¹¹³ Independent risk factors for late mortality were advancing age, neurologic deficit at presentation, and patent false lumen postoperatively. Finally, in the IRAD analysis of long-term survival after acute type A aortic dissection, patients who survived initial surgical repair had 1- and 3-year survival rates of 96% and 89%, respectively.²³⁸ The only significant predictors of late death identified were history of atherosclerosis and previous cardiac surgery. These figures need to be interpreted with caution, however, as the IRAD consortium did not mandate long-term follow-up after initial hospital discharge; late vital status and clinical data were available in approximately half of their patients.

Reoperation

After repair of acute type A aortic dissection, growth rates of the arch and thoracoabdominal aorta have been estimated to be 1 to 5 mm per year by several investigators.^{113,114} As such, despite successful intervention in the acute or chronic phase of the disease, aneurysmal degeneration of the false lumen in other downstream segments of the aorta can occur in a substantial proportion of patients, which can lead to late aortic rupture and death or require reintervention. As discussed previously, aortic root aneurysm, new or recurrent severe aortic regurgitation, and anastomotic false aneurysm are other indications that require repeat surgical intervention. Late reoperations for aortic dissection can be technically challenging, usually require extensive aortic reconstruction, and frequently involve thoracoabdominal aortic repair which have been considered high-risk procedures, especially in the emergency setting.^{10,112,171} More recently, however, reoperative early mortality rates between 4% and 11% have been reported from centers with large experience in thoracic aortic surgery.^{113,114,223,226}

In the Stanford 30-year experience, freedom from late reoperation for patients with acute type A dissections at 1, 5, 10, and 15 years was 94%, 83%, 65%, and 65%, respectively.¹⁰ For chronic type A dissections, these freedom estimates were 96%, 88%, 65%, and 52%, respectively. Younger age was the only significant, independent risk factor portending a higher likelihood of reoperation. In the more recent Stanford report focusing on patients with acute type A dissections, male gender, Marfan syndrome, coronary artery disease, peripheral pulse deficit, and arch involvement were associated with a higher likelihood of late distal aortic reintervention.¹⁸³ Freedom from proximal or distal aortic reoperations after surgical repair of acute or chronic type A aortic dissections in the patients operated on at Stanford University

FIGURE 70-10 ■ Actuarial survival after operative repair of chronic type A aortic dissection in 165 consecutive patients operated on between 1964 and 2000 at Stanford University Medical Center.

FIGURE 70-11 ■ Actuarial freedom from proximal or distal aortic reoperation after operative repair of acute type A aortic dissection in 323 patients operated on between 1963 and 2000 at Stanford University Medical Center.

between 1963 and 2000 is shown in [Figures 70-10 through 70-12](#).

In the Baylor experience, overall freedom from reoperation for patients with all types of dissections was 96%, 91%, and 78% at 1 year, 5 years, and 10 years, respectively.²³⁴ In the Cleveland Clinic series, these respective freedom from reoperation estimates were 98%, 91%, and 85% for patients with type A dissections.²³³ On the other hand, freedom from reoperation after repair of acute type A dissection was 66%, 58%, 52%, and 43% at 1 year, 5 years, 10 years, and 15 years, respectively, in the experience of Loisan and colleagues.²⁴³ In the recent report from the Washington University in St. Louis, freedom from reoperation was 74% at 10 years¹¹⁴; in the University of Pennsylvania experience from 1993 to 2004,

FIGURE 70-12 ■ Actuarial freedom from proximal or distal aortic reoperation after operative repair of chronic type A aortic dissection in 165 patients operated on between 1964 and 2000 at Stanford University Medical Center.

actuarial freedom from any reoperation was 87% at 5 years and 70% at 10 years.²⁴³ Interestingly, using the systematic Mt. Sinai long-term clinical and radiologic follow-up database, the estimated risk of reoperation on the distal aorta was only 16% 10 years after initial surgical repair of acute type A dissection using open arch repair and aggressive resection of the primary intimal tear.¹¹³

Younger age at the initial operation has been a strong risk factor for late aortic reinterventions.^{114,233,243-245} Marfan syndrome has also been associated with a higher risk of recurrent problems in the aortic root as well as the distal thoracic aorta, suggesting that a more radical approach is justified in patients with connective tissue disorders to reduce the incidence of late reoperations.^{113,114,228,243-245} More severe aortic valve regurgitation at the time of the initial operation has been identified by different authors to be a risk factor portending a higher probability of proximal reoperation on the aortic root and valve.^{243,246} The wisdom of using GRF or fibrin glue to reconstruct the dissected aortic root and distal aorta has also been questioned because of its late complications, including false aneurysms.^{175,176,228} Failure to excise the primary intimal tear, leaving behind unresected residual aneurysm at the index operation, and persistent patency of the false lumen have also been linked to a higher incidence of late distal aortic reoperations.^{91,114,229,233,243,245}

Concerning both late survival and need for late reoperation, it remains to be determined whether contemporary surgical techniques of total or partial arch replacement using a distal surgical elephant trunk graft in the descending thoracic aorta or a FET in the distal aortic true lumen will be associated with fewer late deaths and reoperations.^{203-205,209-215} We must learn which patients with acute type A dissections are at highest risk for untoward late complications such that these more aggressive techniques can then be selectively applied to optimize the risk-to-benefit ratio.

FOLLOW-UP

Close medical follow-up and careful periodic imaging surveillance on a rigorous basis are mandatory for all patients with aortic dissections forever. After operative repair, early postoperative serial CTA or MRI of the thoracic and abdominal aorta is essential to define the baseline pathoanatomy and thereafter to detect dissection complications; these scans should be performed at 3- to 6-month intervals during the first year and then every 12 months indefinitely. A transthoracic echocardiogram should also be performed annually to evaluate the aortic root and aortic valve function. Strict long-term blood pressure control is critical for all these patients, as uncontrolled hypertension in the chronic phase of aortic dissection has been associated with an increase in late aortic complications.¹¹⁴ A combination of conventional antihypertensive agents and negative inotropic medications, such as oral beta blockers which have been shown to improve late survival in type A aortic dissection, is required and must be continued indefinitely.²⁴⁷ Antihypertensive drugs such as the angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which paradoxically increase aortic dP/dt, should be avoided, if at all possible; if severe hypertension requires more aggressive therapy and one of these drugs, it is essential that adequate beta blockade be maintained concomitantly.

FOLLOW-UP

Occurring more frequently than ruptured abdominal aortic aneurysm, aortic dissection is the most common catastrophe involving the aorta. Because major aortic branch occlusion can complicate the clinical presentation of patients with acute dissection and thus mimic many other acute medical and surgical problems, a high index of clinical suspicion is necessary to diagnose this life-threatening condition early. The lethal nature of acute aortic dissection mandates prompt medical, interventional, or surgical treatment. In the chronic phase, aortic dissection involving the descending thoracic aorta is responsible for a substantial proportion of thoracic and thoracoabdominal aortic problems requiring surgical repair.

Although a consensus exists today regarding the need for emergency surgical treatment of essentially all patients with acute type A aortic dissection, the optimal management of patients with aortic dissection involving the descending thoracic aorta—medical only versus catheter interventional and medical versus surgical and medical—remains controversial.¹ Most patients with acute type B dissections are treated medically.²⁻⁷ A complication-specific approach is favored by most authorities, reserving surgical replacement or endovascular stent grafting of the descending thoracic aorta for patients with complicated dissections, including rupture, ischemia of vital

organs, persistent pain, uncontrollable arterial hypertension, or sizable dilation of the false lumen.^{2,4,7} On the other hand, we and other groups have also advocated consideration of early surgical treatment for carefully selected patients with uncomplicated acute type B dissection who are young and are otherwise good surgical candidates, including those with Marfan syndrome or other connective tissue disorders, in an attempt to lower the long-term risk of dissection-related complications and aortic reoperation.⁸⁻¹⁰ Since the late 1990s, emergency thoracic endovascular aortic repair (TEVAR) for patients with complicated acute type B aortic dissection has played a major role (see [Chapter 72](#)), occasionally supplemented by catheter interventional flap fenestration and true lumen bare metal stenting to relieve distal malperfusion.^{10,11}

HISTORICAL NOTE

The first surgical attempt to treat acute aortic dissection complications was described in 1935 by Gurin and associates,¹² who used surgical iliac artery fenestration to correct dissection-related lower extremity ischemia. In 1955, DeBakey and colleagues¹³ initiated the modern era of surgical management of aortic dissection by

introducing graft replacement of the dissected thoracic aorta. Subsequently, DeBakey introduced the use of cardiopulmonary bypass during clamping of the descending thoracic aorta.¹⁴ Wheat and associates,¹⁵ in 1965, recommended medical treatment with use of pharmacologic antihypertensive drugs for aortic dissection involving the descending thoracic aorta. The introduction of percutaneous interventional techniques in the early 1990s (e.g., fenestration of the dissection flap and stenting of aortic branches) to alleviate dissection-induced branch vessel compromise and malperfusion modified the traditional indications for surgical treatment, with more patients now being treated medically and interventionally despite the presence of complications that earlier would have prompted emergency operation.¹⁶ The advent of TEVAR in patients with complicated acute type B aortic dissections since 1999 has been associated with promising results.^{17,18} Although TEVAR is now widely used in patients with acute type B dissection following U.S. Food and Drug Administration (FDA) approval of the Gore C-TAG and Medtronic Valiant stent grafts for acute or chronic dissections in 2013-2014, until the long-term durability and effectiveness of TEVAR are confirmed in randomized prospective trials comparing this therapy with standard medical and surgical therapy, the exact role of this new modality in the treatment of uncomplicated acute type B dissection remains unclear.¹⁰

NOMENCLATURE

As described in [Chapter 70](#), various classification methods have been applied to aortic dissection. During the past 45 years, the Stanford functional approach, based on whether the ascending aorta is involved, regardless of the site of primary intimal tear, has gained broad acceptance. If only the descending thoracic aorta is involved, the dissection is called a Stanford type B, DeBakey type III, University of Alabama “descending,” Massachusetts General Hospital “distal,” or Najafi “posterior” dissection.¹⁹⁻²³ Examples of various types and extents of dissections are illustrated in [Figure 70-1](#) in [Chapter 70](#). This consensus has made it easier to interpret and to compare outcomes of various therapeutic strategies reported from various institutions. Aortic dissections diagnosed within 14 days of the onset of presenting symptoms are arbitrarily termed *acute*, whereas those diagnosed more than 14 days after onset are classified as chronic dissections on the basis of the expected biological behavior of the disease process.^{3,5,7,10,23} The term *subacute* has reemerged in the TEVAR era meaning dissections 14 to 90 days old based on the rationale that the dissection flap still remains moldable and dynamic enough that a stent graft usually can remodel the aorta successfully. This term, however, is too ambiguous to convey meaningful clinical discriminatory information and should not be adopted. Intramural hematoma (IMH) and penetrating aortic ulcers (PAUs) are now recognized as distinct pathologic variants of classic aortic dissection.^{24,25} These lesions are characterized by the absence of an intimal flap dividing the aorta into true and false lumens and more commonly involve the descending thoracic aorta. It is

important to distinguish IMH and PAU from classic type B aortic dissection, but these entities constitute a continuum of pathophysiologic changes that can evolve rapidly from one to the other. Furthermore, management of these lesions can differ in certain clinical circumstances.^{26,27}

EPIDEMIOLOGY AND NATURAL HISTORY

Epidemiology

Acute type B aortic dissection more commonly affects middle-aged to older men. Aortic dissection is seen in all age groups, although the peak incidence is found between the ages of 50 and 69 years.^{28,29} Patients with type B dissections are older than those with type A dissections.²⁹⁻³¹ In the Stanford 30-year experience with aortic dissection, the mean age of patients with acute type B dissection was 64 years, compared with 56 years for those with acute type A dissections.³⁰ The estimated male-to-female ratio is between 2:1 and 3:1.²⁹ The prevalence of arterial hypertension ranges from 45% to 80% and is highest in patients with type B dissections.^{3,5,29-32} Associated atherosclerotic vascular disease is also found more frequently in patients with type B dissections.^{29,31} Between 2% and 4% of patients presenting with acute type B dissections have Marfan syndrome.^{29,30}

The incidence of aortic dissection is estimated to be between 5 and 20 cases per million population per year, which is higher than the incidence of ruptured abdominal aortic aneurysms or ruptured thoracic aortic aneurysms.³³⁻³⁵ In a review of the Swedish national health care registers during a 15-year period, the incidence of aortic dissection increased substantially between 1987 and 2002.³⁶ Approximately two thirds of all acute aortic dissections involve the ascending aorta (Stanford type A), with one third limited to the descending aorta (Stanford type B).^{28,30,31}

Natural History

Untreated, acute aortic dissection can be highly lethal. In the 1967 report by Lindsay and Hurst,³⁴ one third of the patients suffering from acute aortic dissection died within 24 hours, 50% within 48 hours, 80% within 7 days, and 95% within 1 month. In patients presenting with chronic dissection, only 15% were still alive after 5 years. These figures, however, should be interpreted only as approximations because none of the retrospective observational or autopsy investigations was able to capture the true denominator of how many patients sustained a dissection. Patients with dissection involving the descending thoracic aorta (Stanford type B), however, had a somewhat less ominous early prognosis; 75% were alive 1 month after onset. Anagnostopoulos and coworkers,³³ in a large collected series of 963 cases of untreated aortic dissection (type A or B, acute or chronic), reported a cumulative mortality of 70% at 1 week and 90% at 3 months.

Patients with untreated type B dissection usually die of aortic rupture in the left pleural space or distal

malperfusion with or without occlusion of major distal aortic branches resulting in ischemic injury to vital organs.³ An autopsy study by Roberts and Roberts³⁷ of 40 patients with acute or chronic type B dissections illustrated that the dissection or its vascular complications caused at least 84% of deaths in the 31 patients who were treated medically. Some fortunate individuals with acute dissections survive untreated; in almost all these cases, distal reentry sites are found, allowing decompression of the false lumen.^{5,32} The patent false lumen remains prone to progressive expansion over time, resulting in the potential formation of a thoracic or thoracoabdominal false aneurysm.

PATHOPHYSIOLOGY

The typical pathologic lesion found in older adult patients with type B aortic dissection is smooth muscle degeneration within the aortic media, in part a normal manifestation of the aging process.³⁸ These findings are distinct from the elastic tissue medial degeneration of the aorta observed in younger patients presenting with type A dissection, which is more frequently associated with heritable connective tissue disorders.³⁹

The initial event in aortic dissection is tearing of the intima.^{5,39} Type B dissections can infrequently also arise from rupture of an atherosclerotic plaque,⁴⁰ but this usually represents a localized dissecting process that does not propagate and produces a characteristic “mushroom cap” appearance on computed tomography (CT) scans; this is a different process from classic type B dissection, which frequently involves most or all of the descending and abdominal aorta. After a primary intimal tear occurs, blood flow within the aortic wall separates the layers of the media and creates the false channel. Propagation of the dissection occurs within the outer third of the aortic media, usually in an antegrade direction, but it may also propagate proximally, or retrograde, to involve the transverse arch. As in type A aortic dissections, distal reentry sites are usually multiple and commonly are located in regions of sheared-off ostia of arterial branches. Factors influencing dissection propagation include the rate of increase of aortic systolic pressure or aortic dp/dt , aortic diastolic elastic recoil pressure, mean arterial pressure, and aortic wall stiffness and intrinsic integrity.^{5,41,42} In the descending aorta and abdominal aorta, the false lumen often spirals along the left posterolateral wall, with the false lumen frequently incorporating the left renal artery.²⁸ The false lumen ordinarily remains patent, especially if reentry fenestrations are present, but it may occasionally thrombose partially or completely if there is a “non-reentering” false lumen; the pressurized and partially thrombosed false lumen can then extrinsically compromise aortic true lumen blood flow distally. Indeed, most distal malperfusion problems can be traced to a non-reentering false lumen. In the chronic phase of dissection, progressive dilation of the patent false lumen results in overall enlargement of the aorta and formation of a false aneurysm. This usually is a diffuse process involving the entire length of the dissection from the arch to the iliac arteries.

FIGURE 71-1 ■ Site of primary intimal tear in 189 patients with acute type B aortic dissection treated at Stanford between 1963 and 1999, broken down into medical and surgical subgroups. (From Umaña JP, Lai DT, Mitchell RS, et al: Is medical therapy still the optimal treatment strategy for patients with acute type B aortic dissections? *J Thorac Cardiovasc Surg* 124:896–910, 2002.)

For aortic dissections involving the descending thoracic aorta, the primary intimal tear is located in the proximal descending thoracic aorta just beyond the origin of the left subclavian artery in approximately 80% of cases, as illustrated in Figure 71-1.^{1,43} In 10% to 20% of patients, the primary intimal tear is located in the transverse aortic arch, and the dissection extends in an antegrade direction to involve variable lengths of the descending aorta or in a retrograde fashion to involve the ascending aorta. When it propagates backwards across the arch and involves the ascending aorta, the dissection is called a retro-A, type A, or Ruel-Cookey-DeBakey type III-D dissection. In less than 5% of aortic dissections, a distinct primary intimal tear cannot be identified; these dissections are usually confined to the descending thoracic aorta.²⁸ In rare cases, the dissection can be limited to the aortic arch without either antegrade or retrograde propagation (isolated arch dissection). It is also estimated that 2% to 4% of aortic dissections may originate in the abdominal aorta.^{44,45}

IMH originates from spontaneous rupture of the vasa vasorum within the outer third of the aortic media, allowing accumulation of blood within the aortic wall in the absence of a large intimal defect.^{24,27} Alternatively, IMH can follow rupture of an atheromatous plaque through the internal elastic lamina, leading to the formation of a PAU, with subsequent extravasation of blood into the aortic wall.²⁵⁻²⁷ In the past 2 decades, major advances in cardiovascular imaging techniques have led to increasing recognition of IMH with or without associated PAU in patients with acute aortic syndromes. Several investigators reported that these lesions can stabilize with medical therapy, but IMH with or without associated PAU can also rupture or evolve quickly into a classic aortic dissection.^{46,47} It is now recognized that IMH involving the descending aorta (i.e., type B IMH) may have a natural history different from that of classic aortic dissection and a higher propensity for aortic rupture, especially in patients with severe acute symptoms or when the IMH is associated with a deep or large PAU.^{26,27,48}

Aortic branch vessel involvement or thoracoabdominal malperfusion results when the dissection compromises blood flow to important downstream aortic tributaries. As illustrated in [Figure 70-4 of Chapter 70](#), the most common mechanisms producing aortic branch compromise are extrinsic compression of the aortic true lumen by the false lumen and an intimal flap compromising the orifice of the branch artery. As defined by Williams and associates,⁴⁹ static branch compromise is extension of the dissection flap into a branch vessel with subsequent mechanical obstruction of flow; conversely, in dynamic branch compromise, the dissection flap prolapses into the vessel origin or the true lumen is narrowed above it because the bulk of flow is in the aortic false lumen. Compression by the large false lumen can thus result in near-obligation of the true channel (true lumen collapse or “obliteration”).⁵⁰ With extension of the dissection, some aortic tributaries may be spared and continue to be perfused by the true lumen; others may be perfused exclusively from the false lumen after being sheared off and eventually become permanently dependent on flow from the aortic false lumen. Thus, clinical presentation is dependent on which aortic branches are involved and on the severity of compromised perfusion, which can be variable, thus confounding and delaying the correct diagnosis. Simultaneous occurrence of a variety of acute clinical problems without a readily apparent unifying cause should prompt consideration of acute aortic dissection.

CLINICAL MANIFESTATIONS

Patients with acute type B dissection can present with symptoms and physical findings that suggest almost any other acute medical or surgical disease process.^{3,23,32} These numerous, nonspecific manifestations are the main reason that the rapid, correct diagnosis of aortic dissection remains such a formidable clinical challenge.^{7,51} Indeed, aortic dissection occurs more frequently than ruptured abdominal aortic aneurysm, but it is diagnosed correctly less frequently antemortem.^{3,23}

Most commonly, the clinical hallmark of acute type B aortic dissection is the acute onset of severe, lancinating chest or back pain.^{3,5,7,23,32} The initial pain can be in any location, but it usually originates in the interscapular region with later migration to the lower back or abdomen. Pain in acute dissection is thought to be secondary to stretching of the aortic adventitia caused by the dissecting hematoma. Abrupt onset of symptoms and description of sharp, ripping, or tearing pain are also characteristic of acute dissection. Persistence or further migration of pain suggests continuing expansion or distal extension of the dissecting process. In rare cases, acute dissection can be painless; vigilance is essential to recognize other manifestations of aortic dissection in these cases. In a summary from the International Registry of Acute Aortic Dissection (IRAD), 98% of 175 patients with acute type B dissection reported some pain, pain was of sudden onset in 84%, and 63% reported chest pain (anterior in 44%, posterior in 41%) that was significantly different from acute type A dissection (chest pain in 79% and anterior

in 71%).³¹ Back pain was observed in 64% and abdominal pain in 43% of patients with acute type B dissections, much more frequently than in patients with type A dissection.³¹ Moreover, the pain was described as the “worst ever” in 90% of patients, sharp in 68%, and tearing in 52%. Radiating pain was observed in 30% of cases, whereas migration was reported in only 19%.

Despite clinical signs of poor peripheral perfusion, elevated blood pressure is usually observed. In the IRAD report, 70% of patients with acute type B dissection were hypertensive at initial presentation; only 4% were hypotensive and in shock, compared with 25% of patients with acute type A dissection. If the patient is hypotensive, aortic rupture should be suspected. Cardiac tamponade is rare in acute type B dissection; only 2% of patients with acute type B dissection in the 30-year Stanford experience had tamponade, which was thought to be the result of leakage of blood and fluid into the pericardial sac from a large, high-pressure mediastinal hematoma.³⁰

The constellation of other symptoms and signs relates largely to which distal aortic branches are involved in the dissection. Approximately 25% of patients present with symptoms related to aortic branch compromise or develop such symptoms early in the course of their illness⁵²; alternatively, loss of a peripheral pulse may be clinically asymptomatic. In a review of the Stanford experience with peripheral vascular complications of aortic dissection by Fann and colleagues,⁵³ 85 (31%) of 272 patients with all types of dissections sustained at least one peripheral vascular complication, whereas 20% of patients with type B dissections had such complications ([Fig. 71-2](#)). Of the 85 patients with a vascular complication, 18 individuals (21%) suffered two complications, and 7 (8%) had three or more vascular problems. Among the 40 patients with acute type B dissection, no patient presented with a stroke, 3% had acute paraplegia at presentation, 20% sustained loss of one or more peripheral pulses, 8% had impaired renal perfusion demonstrated angiographically, and 5% had compromised visceral perfusion by angiography. The incidence of these complications with the attendant operative mortality rate after surgical graft replacement of the descending thoracic aorta is summarized in [Table 71-1](#). The distribution of specific sites of peripheral pulse loss in these patients is summarized in [Table 71-2](#). Others authors have reported similar figures, with the prevalence of peripheral vascular manifestations ranging from 10% to 30%.^{5,21,52,54,55} As a general rule, morbidity and mortality rates are higher in patients presenting with branch vessel involvement.^{29,52}

The clinical course of peripheral limb ischemia can vary; up to one third of patients may experience spontaneous resolution of the peripheral pulse deficit or a fluctuating course, often because of the reentry of flow into the distal true lumen from the false lumen.⁵⁴ Stroke and transient ischemic attack can complicate acute type A dissection but are seen only rarely in patients with type B dissections. Neurologic findings can vary from minor sensory deficits to frank paraplegia resulting from spinal cord ischemia caused by interruption of intercostal artery blood supply to peripheral ischemic neuropathy.^{32,52} Abdominal pain out of proportion to the physical abdominal findings must be considered potentially to reflect

FIGURE 71-2 ■ Examples of diagnostic computed tomography (CT) scans. **A**, The CT scan shows the linear flap (black lucency, white arrow) between the two aortic lumens in the descending thoracic aorta that is characteristic of aortic dissection. In addition, a relatively large hematoma surrounding the aorta is seen (arrowheads), representing recent hemorrhage contained in the posterior mediastinum. Despite this ominous appearance, this patient did well with medical therapy for more than 1 year until progressive enlargement of a localized false aneurysm prompted referral for operation. **B**, CT scan from a different patient with an acute type B dissection illustrating a false aneurysm involving the distal arch and proximal descending thoracic aorta. The false lumen (arrowheads) is partially thrombosed; therefore, it opacifies only faintly compared with the contrast seen in the true lumen (arrow). **C**, Although this patient had a type A dissection (note the deformed true lumen in the large ascending aorta), this CT scan demonstrates differential opacification of the true and false lumens in the descending thoracic aorta. The true lumen (arrow) is completely opacified in the left panel; later in the cardiac cycle (right panel), both true and false lumens are equally opacified. (From Miller DC: Acute dissection of the descending thoracic aorta. *Chest Surg Clin North Am* 2:347–378, 1992.)

TABLE 71-1 Peripheral Vascular Complications and Associated Operative Mortality Rates in a Series of 40 Patients with Complicated Acute Type B Aortic Dissection

Peripheral Vascular Complication	Prevalence (n)	Mortality (n)
Stroke	0% (0)	—
Paraplegia	3% ± 3% (1)	100% (1)
Pulse loss	20% ± 8% (8)	50% ± 18% (4)
Renal ischemia	8% ± 4% (3)	67% ± 28% (2)
Visceral ischemia	5% ± 3% (2)	50% ± 37% (1)

mesenteric ischemia or infarction, which must be confirmed or ruled out expeditiously.⁵⁴ Oliguria or anuria suggests renal perfusion compromise; flank pain or hematuria caused by renal malperfusion or infarction can mimic symptoms usually associated with ureteral colic or kidney stones.

Physical examination of patients with suspected aortic dissection should include measurement of blood pressure in both upper and lower extremities. A complete evaluation of peripheral pulses is imperative, in addition to a comprehensive motor and sensory neurologic examination. The patient should be reexamined periodically because new vascular or neurologic deficits may come and go. The remainder of the physical examination is often normal.

Most patients with *chronic* type B dissection are asymptomatic. However, progressive enlargement of the aortic false lumen may eventually produce compression, obstruction, or erosion into adjacent thoracic structures, producing symptoms such as chest pain, dyspnea, wheezing, hoarseness, dysphagia, hemoptysis (aortobronchial fistula or erosion into the lung), and hematemesis (aorto-esophageal fistula) and symptoms secondary to compromised flow in an important distal aortic branch.

DIAGNOSTIC MODALITIES

Definitive diagnostic procedures should be performed as expeditiously as possible to confirm the diagnosis of acute type B aortic dissection. Before the widespread availability of newer imaging techniques, the diagnosis was generally made by conventional catheter aortography. Today, much better options include multislice computed tomographic angiography (CTA), transesophageal echocardiography (TEE), and magnetic resonance imaging (MRI). Chest radiography is neither sensitive nor specific. The imaging modality chosen should determine the type of dissection and its extent, the site of the primary intimal tear, and the presence or absence of major aortic branch compromise. More than one imaging study may be necessary to confirm the diagnosis or to identify additional pathoanatomic details; in IRAD, multiple imaging studies were needed in 76% of patients, and an average of 2.2 imaging studies were carried out in patients with acute type B dissection before definitive treatment.^{31,52}

CT scanning has markedly facilitated the rapid and accurate diagnosis of acute aortic dissection. In most cases, a thin-slice spiral CTA with intravenous administration of contrast material can determine rapidly and noninvasively the dissection type (type A or B), as illustrated in Figure 71-2. The extent of dissection, the perfusion status of individual aortic branches, and the size of the true and false lumens in all aortic segments can also be assessed accurately. Identification of two distinct lumens in the descending thoracic aorta separated by an intimal flap confirms the diagnosis of type B aortic dissection.⁵⁶ Other important signs include compression of the true lumen by the false lumen, displaced intimal calcification, thrombosed false lumen, nonopacified crescent-shaped area along the aortic wall (IMH), and ulcer-like projection of contrast material within the aortic wall indicating a PAU.⁵⁷ The presence or absence of pericardial or pleural effusions is also defined. The sensitivity and specificity, respectively, of CTA in making the diagnosis of acute type B aortic dissection are between 82% and 100% and 89% and 100%.^{*} In the 1993 study by Nienaber and coworkers⁵⁹ that prospectively evaluated noninvasive modalities in 110 patients with suspected acute dissection, the sensitivity and specificity of CT scanning were 96% and 89% in patients with type B dissection; the positive and negative predictive values were 80% and 98%, respectively. A drawback associated with CT scanning is the requirement for administration of intravenous contrast material in patients with impaired renal function.

In most centers worldwide, TEE and/or CTA are the diagnostic modalities of choice in patients with suspected type B aortic dissection, and many patients do not require additional corroborative studies.[†] TEE is rapid, convenient, and noninvasive and can be performed in the emergency department, in the intensive care unit, or in the operating room with minimal risk. Undesirable blood

pressure elevation is a potential risk of TEE, mandating adequate sedation of the patient. Multiplanar, phased array TEE with color flow imaging can accurately demonstrate flow in both aortic channels and the flap separating the true and false lumens; real-time three-dimensional TEE imaging can provide spectacular surface-rendered images. The most important finding is identification of an intimal flap, ideally seen in more than one view, oscillating independently of the motion of the aortic wall.^{56,59,61,63} Frequently, the primary intimal tear and secondary fenestrations in the descending thoracic aorta can also be identified. Overall, the sensitivity and specificity of TEE in the evaluation of suspected type B aortic dissection are between 97% and 100% and 94% and 98%, respectively.[‡] Limitations of TEE include dependence on an experienced interpretation of the findings and limited capability to assess abdominal branch vessel involvement and extent of the dissection below the diaphragm; if the patient is very small or very thin, as in Japan, the takeoff of the celiac axis, superior mesenteric artery, and occasionally one or both renal arteries can be visualized with TEE.

Currently, MRI does not play a major diagnostic role in patients with acute dissection because these individuals are often critically ill and connected to various monitoring devices, infusion pumps, or respirators.^{7,32} In the acute setting, the limited 24-hour availability, the relatively long time necessary for image acquisition, and the limited access to the patient during the procedure make MRI much less practical than other diagnostic modalities. Nevertheless, MRI can delineate noninvasively the entire thoracoabdominal aorta and demonstrate the intimal flap, both aortic channels, and involvement of major aortic branches. As with CTA, the most important criterion for the diagnosis of acute aortic dissection with MRI is the identification of two distinct flow lumens separated by an intimal flap.⁵⁶ Many investigators have reported that MRI is associated with high sensitivity and specificity in the evaluation of suspected aortic dissection, both in the range of 95% to 100%.[§] For suspected acute type B dissection, Nienaber and coworkers⁵⁹ observed that MRI had a sensitivity of 97% and a specificity of 100%. Today, magnetic resonance scans are most useful for serial, long-term follow-up of patients with chronic aortic dissections, including postoperative patients and those initially treated medically.

Contrast aortography historically was the “gold standard” in the diagnosis of aortic dissection (Fig. 71-3).⁶⁵ Angiography, however, is invasive, is time-consuming, and necessitates the use of contrast material; moreover, it is not infallible, and the technique carries a risk of morbidity and mortality, but it can provide detailed information about perfusion status of important aortic branches.^{32,56,66} Angiographic diagnosis of acute dissection requires identification of a double lumen or an intimal flap; indirect signs that are suggestive of an acute dissection include compression of the true channel by an expanding false lumen, thickening of the aortic wall,

FIGURE 71-3 ■ Aortographic findings in acute type B aortic dissection. The true aortic lumen (T) is extrinsically narrowed by the false lumen (F). The true lumen is characteristically smaller and located medially. Note that the pigtail angiographic catheter has been passed up the true lumen from below. The primary intimal tear (arrow) is located just distal to the left subclavian artery.

ulcer-like projection in the aortic wall (in cases of penetrating atherosclerotic ulcer), and abnormal position of the guidewire or catheter in the aorta.^{26,27,56,65} Biplane angiographic studies of the thoracic aorta are mandatory because single-plane aortography can miss important findings; false-negative results can also occur when the false lumen is thrombosed and in cases of IMH.^{5,27,56} The sensitivity and specificity of aortography in the evaluation of aortic dissection range between 80% and 90% and 85% and 95%, respectively.^{5,7,29,56} Currently, aortography is reserved for patients with acute type B dissection presenting with clinical evidence of malperfusion or those with persistent peripheral vascular complications after proximal aortic repair to delineate the mechanism of aortic branch vessel compromise and guide subsequent appropriate endovascular interventions to restore distal perfusion.^{||}

MANAGEMENT

Strategy

The aim of therapy in patients with aortic dissection is to prevent death and irreversible end-organ damage. As discussed in [Chapter 70](#), almost all patients with acute type A dissection should be considered for emergency surgical repair of the ascending thoracic aorta.^{2,3,5,7} In contrast, the optimal treatment strategy for patients

BOX 71-1 Firm or Relative Indications for Surgical or Endovascular Intervention in Patients with Acute Type B Aortic Dissection

- Persistent pain
- Refractory arterial hypertension
- Progression or expansion of dissection
- Aortic rupture or impending rupture
- Evidence of impaired distal organ perfusion
- Sizable localized false aneurysm
- Connective tissue disorders (Early surgical intervention to be strongly considered)

with acute type B dissection continues to be debated.[¶] In 1965, Wheat and Palmer and colleagues¹⁵ recommended medical “anti-impulse” therapy for acute aortic dissection, and in 1970, Daily and colleagues²⁰ from Stanford concluded that there was no major difference in early outcome between patients treated medically and those treated surgically. The rationale behind medical management is based on three observations: (1) medical therapy prevents early death in most patients^{1,5-7,31,73}; (2) operative mortality for patients with acute type B dissections requiring emergency operations has been relatively high^{6,7,31,43}; and (3) long-term outcome has been similar for patients treated medically or surgically.^{1-3,6,7,73}

Today, most groups favor a complication-specific approach for patients with acute type B dissections ([Box 71-1](#)), reserving surgical or endovascular intervention on the descending aorta for those with rupture, thoracoabdominal malperfusion, impending rupture, or other life-threatening complications. In the past, other “soft” indications included persistent pain and refractory hypertension, but these are too subjective and have been discarded by the FDA in the new registries for TEVAR.^{1-7,10,11,70,71} These are clinical indications and do not include offering asymptomatic patients a semi-elective TEVAR simply because it may help promote aortic remodeling over time, as was the case in the INSTEAD trial.^{74,75} On the other hand, we and some other groups have advocated consideration of early surgical replacement of the descending aorta for selected patients with acute type B dissections who are young and otherwise good operative candidates, irrespective of the presence or absence of complications; this includes predominantly patients with connective tissue disorders such as Marfan syndrome and Loeys-Dietz syndrome.^{7-9,68,76,77} If the operation is successful, these patients theoretically should be at lower risk of sustaining late dissection-related complications or requiring aortic reoperation.

The Stanford aortic dissection classification concept has also been applied to IMH because the prognostic impact of the location and its treatment have been considered comparable to those in patients with a classic aortic dissection.^{27,47,78} It is generally accepted that patients with IMH involving the descending thoracic aorta (type B IMH) can usually be successfully managed conservatively with aggressive blood pressure control in

^{||}References 16, 17, 29, 55, 56, and 67.

[¶]References 1-10, 17, 18, 20, 32, and 68-72.

the absence of disease progression.** Several groups have reported, however, that the prognosis of markedly symptomatic patients with penetrating ulcers located in the descending thoracic aorta and type B IMH coexistent with a deep PAU was worse than the prognosis of those with classic aortic dissection because of a higher incidence of aortic rupture.^{26,27,48} In these cases, early surgical or endovascular treatment should be considered, especially if persistent pain, increasing pleural effusion, and a large, deep PAU are present.

Initial Medical Treatment

As soon as acute aortic dissection is suspected, emergency medical therapy should be initiated and continued while the diagnostic procedures are performed.^{5,7,32} The cornerstone of modern medical therapy, as originally described by Wheat and collaborators, is reduction of mean, peak, and diastolic recoil arterial pressure and the rate of rise of arterial pressure or aortic dP/dt (*not* left ventricular dP/dt) to the lowest acceptable level while adequate cerebral, coronary, and renal perfusion is maintained.^{5,7,14,15,29} The goals of medical treatment are to relieve pain, to control systemic blood pressure, and to limit extension of the dissection. Reasonable targets are a heart rate less than 60 bpm and a systolic blood pressure between 100 and 120 mm Hg.¹⁰ Intensive, continuous monitoring of the patient in an intensive care unit is important, including electrocardiography and insertion of indwelling radial or femoral arterial and central venous lines. A urinary bladder catheter and a pulse oximeter are used. Intravenous beta blockers (e.g., esmolol, metoprolol, labetalol, propranolol) are administered in small boluses or as a continuous intravenous infusion; if needed, an intravenous vasodilator infusion, most commonly sodium nitroprusside, is then added. Labetalol, an α_1 -adrenergic and nonspecific β -adrenergic antagonist, is a good alternative to a combination of agents. Parenteral calcium channel antagonists, such as diltiazem, nifedipine, and nicardipine, that lower arterial blood pressure and left ventricular dP/dt can also be used. It must be remembered that because sodium nitroprusside, angiotensin-converting enzyme inhibitors (e.g., enalapril, lisinopril), and angiotensin receptor blockers are pure arteriolar vasodilators, these agents increase aortic dP/dt; therefore, concomitant administration of a negative inotropic agent is essential. If surgical intervention or percutaneous endovascular treatment is carried out, antihypertensive and negative inotropic therapy is continued during anesthetic induction, intraoperatively, and postoperatively.

Definitive Long-term Medical Management

Whether the patient is initially treated medically or surgically, the intravenous antihypertensive and negative inotropic drugs are gradually transitioned to oral agents during the hospitalization. An oral beta blocker (e.g., labetalol, metoprolol succinate [Toprol-XL], atenolol)

or, if a beta blocker is not tolerated, a calcium channel antagonist like verapamil or nicardipine is preferentially used and continued indefinitely, complemented by an oral angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker. Recent data from the IRAD investigators suggest that the use of a calcium channel antagonist at discharge from the hospital was associated with improved long-term survival in patients with type B aortic dissection treated medically.⁷⁹ Because it is incorporated into mucopolysaccharides of the media and may weaken the aortic wall,⁷ hydralazine should be avoided, as should any drug that increases aortic dP/dt. Conversely, there is some unpublished evidence (Harry C. Dietz, Johns Hopkins University, personal communication) that in genetic mouse models of the Marfan syndrome, hydralazine has salutary effects on aortic wall remodeling.

OPERATIVE APPROACH

Acute Type B Dissections

The goal of surgical treatment of patients with acute type B aortic dissection is graft replacement of a limited segment of the descending thoracic aorta, including the site of the primary intimal tear.⁷ At Stanford, after induction of general anesthesia, insertion of a double-lumen endobronchial tube, and usually a lumbar intrathecal catheter for cerebrospinal fluid drainage, patients with acute type B dissections are explored through a left posterolateral thoracotomy.^{7,66} Our preference calls for total cardiopulmonary bypass (CPB) by advancing a long right femoral venous catheter into the right atrium from the *right* femoral vein and, if possible, *antegrade* arterial CPB perfusion. This can be accomplished using a short 6-mm vascular graft sewn end to side to the left subclavian or left carotid artery; inserting an arterial cannula into the undissected ascending aorta or arch or into the descending aortic true lumen and advancing it using TEE guidance over a guidewire into the ascending aorta, or into the left ventricular apex and across the aortic valve (Wada and Kazui method of left ventricular apical aortic CPB perfusion); fluoroscopically manipulating a long, small venous cannula (e.g., 15 Fr) over a stiff guidewire up into the undissected ascending aorta or arch via the femoral artery; or, as a last resort, cannulating the femoral artery on the side that is perfused by the aortic true lumen (almost always the one with the reduced or absent pulse).^{80,81} On occasion, if a venous cannula cannot be passed from the femoral vein, an angled venous cannula can be placed through the main pulmonary artery into the right ventricle to provide (or to augment) venous CPB return. Moderate systemic hypothermia (bladder temperature, 25° to 28° C; tympanic membrane temperature, 20° to 22° C) is generally used such that an open proximal anastomosis can be performed in the distal arch during a brief period of hypothermic circulatory arrest. After the open proximal anastomosis is completed, reperfusion to the head and heart is then immediately started using a side limb off the aortic graft or inserting a metal right-angle cannula into the proximal graft. Hypothermic circulatory arrest is also used in almost all cases of chronic type B dissections to facilitate

**References 9-10, 24, 27, 29, 30, 47, and 78.

the proximal anastomosis in the arch, allowing the chronic arch flap to be safely excised along with evacuation of any thrombus in the false lumen. The circulatory arrest times are longer and unpredictable in these chronic cases, and having the left carotid artery cannulated for antegrade selective cerebral perfusion can be useful (the Siena technique popularized by Neri and coworkers).^{82,83} The patient is placed in a steep Trendelenburg position, and uncontrolled venous retroperfusion backward up the venous cannula at 500 to 1000 mL/min is used during hypothermic circulatory arrest to keep the left side of the heart and ascending aorta free of air. Some of this venous retroperfusion trickles back down into the arch through the arch branches. No preliminary proximal or distal aortic dissection is done, and no aortic cross-clamps are applied either proximally or distally. When the pump is turned down, the proximal aorta is opened and transected after mobilization of the phrenic, vagus, and recurrent laryngeal nerves. In acute type B cases, an open proximal anastomosis is performed with a 4-0 BB 54-inch or 5-0 C1 polypropylene suture incorporating a full-thickness aortic cuff (thereby reapproximating the aortic intima and adventitia and obliterating any proximal false lumen) at the distal arch level. An arterial perfusion cannula is then inserted directly into a single side branch of the aortic graft. After arch de-airing, CPB perfusion to the head and the heart is resumed, with care taken to evacuate any air trapped in the heart or ascending aorta. After 5 to 10 minutes of cold CPB reperfusion, systemic warming is started. Proximal intercostal arteries are oversewn. A conservative segment of descending aorta containing the primary intimal tear and the most severe associated injury is replaced with a woven double velour Dacron Hemashield graft. Continuous 4-0 BB or 4-0 SH-1 polypropylene suture and use of deep suture bites—again, with care to incorporate both aortic layers and to obliterate the false lumen in acute dissection cases—is used for the distal anastomosis.⁷ Although we have avoided using Teflon felt for the past 20 years at Stanford, the proximal or distal aorta can be reinforced with strips of Teflon felt or bovine pericardium or, alternatively, by using a small amount of tissue adhesive between the dissected layers, such as BioGlue (CryoLife, Inc., Kenneraw, GA). The proximal cross-clamp is released, air is evacuated, and the anastomoses are checked for hemostasis. After systemic rewarming to a target of 35° to 36° C, CPB is discontinued. Protamine sulfate is administered after all anastomoses are judged to be technically satisfactory with minimal bleeding. Platelets, fresh-frozen plasma, and cryoprecipitate are used if diffuse hemorrhage from suture lines and raw surfaces are evident after a normal activated clotting time is achieved if abnormal coagulation parameters are identified through use of rotational thromboelastography.

Postoperative management of the patient involves intensive monitoring, including serial abdominal, neurologic, and pulse examinations, as well as strict blood pressure control. Cerebrospinal fluid is drained continuously to keep cerebrospinal fluid pressure lower than 10 mm Hg. In patients without spinal cord injury, the drain is removed on the second or third postoperative day. With use of partial CPB (without hypothermic circulatory arrest in that era) and confining the extent of resection to a short aortic segment, the incidence of new

postoperative paraplegia in our earlier experience was only 4% in patients with acute type B dissections.⁴³ We believe that our current method using hypothermic circulatory arrest for an open proximal anastomosis has reduced the incidence of stroke and spinal cord injury.

Management of Peripheral Vascular Complications

The Stanford approach in patients presenting with aortic dissection and ischemic peripheral vascular complications before the advent of endovascular stent grafts (TEVAR) was to proceed initially with surgical repair of the thoracic aorta because central aortic repair usually obviated the need for peripheral revascularization procedures.^{7,53} The operative mortality rate for patients with all types of peripheral vascular compromise was no higher than that for those without such complications; however, visceral ischemia and impaired renal perfusion portended a high risk of death. If persistent mesenteric, renal, or limb ischemia was detected after thoracic aortic repair, surgical fenestration of the distal descending thoracic aorta or suprarenal abdominal aorta or direct revascularization was traditionally attempted as a lifesaving maneuver.^{7,53,54,84} Today, percutaneous endovascular treatment is the preferred initial intervention in cases of postoperative malperfusion and also in high-risk patients with complicated acute type B dissections (see [Chapter 72](#)).¹¹ Endovascular interventions using bare stents in the collapsed true lumen in the aorta or one of its branches or flap fenestration of the aortic dissection flap (to increase flow in the distal true lumen by decompressing the false lumen) can usually reestablish adequate end-organ perfusion in most cases.^{49,85} These endovascular approaches are described in detail in [Chapter 72](#). In the past 2 decades, endovascular stent grafts have been used increasingly in patients with complicated acute type B dissections to cover the primary intimal tear in the thoracic aorta and to restore blood flow in the distal aortic true lumen, which can be “obliterated” or “collapsed”; this successfully relieved distal ischemia in 76% of all compromised aortic branches (and 100% of those with dynamic obstruction).^{17,86}

Endovascular Stent Grafts

Since 1996, endovascular stent grafts have been used in selected patients with acute type B aortic dissections at Stanford.¹⁷ The Stanford University and Mie University combined series showed that endovascular stent graft repair in patients with complicated acute type B dissections was associated with an encouraging early mortality rate of only 16%. The long-term effectiveness and durability of this new therapeutic approach, however, remain unknown. In 2008 and 2010, the Society of Thoracic Surgeons and the American Heart Association published practice guidelines for the management of patients with descending thoracic aortic disease. These guidelines include potential indications for endovascular stent graft treatment based on existing observational studies and opinions of experts.^{10,11,87} Acute type B aortic dissection

^{††}References 10-11, 49, 50, 55, 85, and 86.

with life-threatening complications and acutely symptomatic IMH with or without penetrating ulcer of the descending thoracic aorta were identified as situations in which endovascular stent graft repair seemed justified.^{10,87} Endovascular stent graft coverage of the primary intimal tear, however, is more a temporary resuscitation therapy allowing stabilization of very sick patients rather than a curative procedure; late complications and the need for reintervention are not unusual. Nonetheless, emergency stent grafting can be lifesaving in patients with severe malperfusion even though the therapeutic goal is not to eliminate all blood flow from the false lumen, as is the case in treating thoracic aortic aneurysms. Later sequelae of the dissection can be treated definitively with open surgical repair or additional endovascular interventions if necessary when the patient is not in extremis. Rigorous prospective controlled comparison of this interventional stent graft approach with conventional emergency surgical treatment (for complicated type B dissections) or with medical therapy (for uncomplicated type B dissections) is not yet available. One study, the INSTEAD trial, enrolled 140 patients with uncomplicated subacute or chronic (14 to 52 weeks) type B aortic dissections who were randomized to best medical therapy versus stent graft treatment. All-cause mortality at 2 years was higher in the stent graft limb group, but the difference did not reach statistical significance.⁷⁴ Additionally, freedom from aorta-related mortality and freedom from progressive aortic disease (a composite endpoint for aortic death, conversion, or additional intervention) was comparable between groups. Despite the absence of clinical benefit, thoracic false lumen thrombosis occurred in 91% of the patients in the stent graft group versus 19% of those receiving medical therapy, a highly significant difference. A recent update of INSTEAD reported significantly lower aorta-related mortality and disease progression (a composite endpoint for conversion, additional intervention, or aortic expansion) at 5 years in the stent graft treatment arm.⁷⁵ The ADSORB trial, a second randomized study, compared treatment with a Gore TAG stent graft versus best medical treatment alone in 61 patients with acute (<2 weeks) uncomplicated type B dissections.⁸⁸ The study endpoints had to be changed and the trial ended prematurely because of inadequate patient enrollment rates. There were no differences in clinical outcomes, including death, at 1 year, but false lumen thrombosis in the descending thoracic aorta occurred much more frequently in the TEVAR subgroup than in the medically treated subgroup (57% vs. 3%). Endovascular stent graft treatment of aortic dissection is discussed in detail in [Chapter 72](#).

Chronic Type B Dissections

Surgical intervention for patients with chronic type B dissection is considered when they have symptoms related to the dissection (e.g., pain or symptoms secondary to compression of adjacent anatomic structures, renovascular hypertension [with or without renal dysfunction], mesenteric ischemia, claudication) or if documented expansion of the false lumen occurs. Asymptomatic patients with large chronic aortic dissections (exceeding 55 to 60 mm in diameter) are also offered surgical graft replacement if they are reasonable surgical candidates. In

addition to maximal aortic diameter and symptoms, consideration of other risk factors that modulate the expected risk of aortic rupture, such as increasing age, connective tissue disorders, uncontrolled hypertension, and chronic obstructive pulmonary disease, is also important to determine the optimal timing for operation and to enhance selection of patients.^{89,90}

Open operative surgical graft replacement is conducted similarly to that described before for patients with acute type B aortic dissections, including our CPB perfusion strategy. In these chronic dissection cases, it is even more important whenever feasible to avoid retrograde arterial CPB perfusion from the femoral artery during systemic cooling, as this can blow debris and thrombus from the aortic true or false lumen up into the arch branches and brain or coronary arteries. Furthermore, retrograde femoral arterial CPB perfusion in patients with a chronic dissection is uncontrolled and unpredictable because CPB flow may not necessarily reach all important aortic tributaries, depending on dynamic motion of the dissection flap and local pathoanatomic factors. Deep hypothermic circulatory arrest also makes reattachment of important lower intercostal arteries as Carrel patches safer and helps protect the visceral organs and spinal cord. If the entire thoracoabdominal aorta (Crawford extent II) is being replaced, as is often necessary in young patients with connective tissue disorders and chronic type A or B aortic dissection, we cool the patient to 15° to 20° C (bladder), and CPB rewarming is not begun until all important intercostal arteries have been reimplanted down to the level of the celiac axis. CPB reperfusion is commenced both proximally (with a cannula inserted into a side branch of the proximal graft) and from below with use of either a femoral artery or a cannula in the distal thoracoabdominal aorta graft after completion of the most distal aortic or iliac anastomosis. In chronic dissection cases, we excise the dissection flap in the arch proximally and in the distal descending thoracic aorta. Because the chronic dissection usually extends down into the abdominal aorta, in replacing only the descending thoracic aorta, we frequently use the “elephant trunk” graft technique distally such that if downstream thoracoabdominal aortic replacement should become necessary, the new graft is simply sewn to the dangling elephant trunk graft proximally. It is important in using an elephant trunk graft in patients with aortic dissections to make sure that the dissection flap distally has been excised for a distance exceeding the length of the planned elephant trunk graft to avoid inadvertent trapping of the graft into one lumen or the other.

RESULTS

Comparison of Results of Surgical and Medical Treatment

Historical Perspective

The controversy about the optimal therapy for patients with aortic dissections dates to the 1960s, when DeBakey and colleagues reported results in 179 patients treated surgically with an early mortality rate of 21% and a

5-year survival rate of 50%.⁹¹ DeBakey and colleagues concluded that all patients with aortic dissection should undergo surgical intervention. Importantly, careful inspection of this paper subsequently revealed a skewed patient population; only 38% of the patients had an acute dissection, and most had a DeBakey type III (Stanford type B) dissection. Wheat and Palmer and colleagues¹⁵ then proposed a selective approach to the management of patients with acute dissection, arguing for medical treatment with a combination of agents that decreased arterial blood pressure and also the rate of rise of aortic pressure (aortic dP/dt). In 1970, Daily and colleagues²⁰ introduced the Stanford type A/B dissection classification system and observed no major difference in early outcome in patients with type B dissections treated medically or surgically. In a 1979 Stanford paper, the early results from 11 studies published in the 1970s were analyzed. The overall mortality rate in this era was 33% in medically treated patients (range, 21% to 67%), and the average operative mortality rate for patients with acute type B dissections treated surgically was 36%.⁹² Of course, the patient cohorts differed considerably, which confounded critical comparison of outcomes. Thereafter, the consensus opinion has been that most patients with acute type B dissections should be treated medically, unless life-threatening dissection-related complications are present.^{††}

Contemporary Comparative Studies of Surgical versus Medical Treatment

No prospective controlled trials comparing surgical with medical management of patients with acute type B dissections have been carried out; however, comprehensive comparative retrospective analyses, including a 2002 report by Umaña and associates from Stanford, have been published.^{1,6,39} Strict interpretation of the results of these two treatment modalities is difficult because of a marked disparity in the clinical characteristics of the medical and surgical cohorts, which created a pronounced selection bias. In most series, patients with uncomplicated acute type B dissections are treated medically, whereas those presenting with life-threatening complications or developing complications while being treated medically are treated with TEVAR.

A 1984 report from the Massachusetts General Hospital concluded that early survival in patients presenting with an acute type B dissection was determined primarily by the number and severity of presenting complications due to the dissection, irrespective of mode of treatment.³⁹ In the 1989 combined Stanford and Duke University study, 136 patients with acute type B dissections between 1975 and 1988 were treated medically (63%) or surgically (37%); patients treated medically tended to have more comorbidities or renal disease, whereas those in the surgical cohort were more likely to have aortic rupture or arch involvement.^{6,71} Sequential analyses were performed to adjust for differences in baseline characteristics to separate patients with acute dissections into three

subgroups: all patients (subset I), patients presenting without compelling indications for emergency operation (subset II), and those individuals from subset II who did not have severe comorbidities (subset III). This last cohort represented low-risk, uncomplicated patients who could have been treated either medically or surgically. For all patients, the statistically significant independent determinants of overall mortality were aortic rupture, other dissection-related complications, increasing age, and cardiac disease. Treatment method was not a predictor of outcome in any subset. In the low-risk subset of patients (subset III), moreover, the early mortality rate was similar between the medically and surgically treated patients (16% vs. 9%), as was the long-term survival rate. More recently, a 36-year review of the Stanford experience including 189 patients with acute type B dissections used propensity score analysis to identify subsets of patients treated either medically or surgically who were at similar risks of death. The impact of treatment method on survival, reoperation, and late aortic complications or death was then determined in these more homogeneous samples to neutralize bias.¹ This statistical analysis identified 142 well-matched patients who did not have any compelling emergency surgical indications (111 were treated medically and 31 underwent operation). Long-term survival was similar in the two matched groups. Freedom from aortic reintervention and from late aortic complication or death was also comparable between the medically treated and surgical subsets. In all patients, multivariable analyses did not identify treatment method as a predictor of outcome; instead, patient-related factors and dissection-specific complications determined the prognosis.

Current Results

Early Survival

During the past 30 years, advances in diagnostic imaging modalities, medical critical care, anesthetic expertise, and surgical techniques have allowed clinicians to make the definitive diagnosis more quickly and have improved early survival rate of patients with acute type B aortic dissection treated medically or surgically.⁸⁸ In the 2000 IRAD review of 175 patients with acute type B dissections treated in 12 centers between 1996 and 1998, the 30-day mortality rate was 11% in medically treated patients and 31% in patients who underwent surgery; of course, the two patient cohorts were markedly different.³¹ Similarly, in two more recent IRAD reports focusing on a large cohort of patients with acute type B aortic dissection, it was shown that the early mortality rate of patients treated medically was now lower than 10%; those requiring surgical intervention for acute aortic dissection-related complications, including aortic rupture and shock, had an early mortality rate closer to 30%.^{98,99} Interestingly, in the small group of patients treated with endovascular TEVAR for complicated aortic dissections, in-hospital complications occurred in 20% (compared

FIGURE 71-4 ■ Early (30-day) mortality rates illustrated as a function of time (decades) and broken down into medical and surgical subgroups in the overall Stanford experience. (From Umaña JP, Lai DT, Mitchell RS, et al: Is medical therapy still the optimal treatment strategy for patients with acute type B aortic dissections? *J Thorac Cardiovasc Surg* 124:896-910, 2002.)

with 40% of the patients treated surgically) and the mortality rate was only 11%, both significantly lower than after surgical treatment.⁹⁹ In the 2002 Stanford paper, the early mortality rate for patients treated medically did not change significantly between 1970 and 1999, ranging from 10% to 19% (Fig. 71-4).¹ On the other hand, the early mortality rate for patients treated surgically decreased from 57% in the 1960s to 27% in the 1990s. Other centers with special expertise in thoracic aortic surgery also demonstrated that early mortality rates closer to 20% can be achieved in the current era in selected patients with acute type B dissections.^{10,100} In an earlier Stanford investigation, multivariable analysis revealed that the independent determinants of operative risk in patients with type B dissections (acute or chronic) were renal or visceral ischemia, aortic rupture, and older age.⁴³ Acute type B dissection caused by an intimal tear located in the arch, whether the patient was treated medically or surgically, was associated with high early mortality rates in a subsequent Duke-Stanford cooperative 1989 report.⁶ In Crawford's surgical experience, the independent risk factors portending operative death were earlier year of operation, surgery within 24 hours of onset of symptoms, and chronic obstructive pulmonary disease.⁹⁵ In the IRAD registry, independent predictors of in-hospital mortality in the overall cohort were hypotension or shock, absence of pain on presentation, and branch vessel involvement; age older than 70 years and hypotension or shock were independent predictors of mortality in the subgroup of patients requiring surgical intervention.^{52,98}

Late Survival

In the 36-year overall Stanford experience, actuarial survival for the entire patient cohort was 71%, 60%, 35%, and 17% at 1 year, 5 years, 10 years, and 15 years, respectively.¹ As illustrated in Figure 71-5A, there was no significant difference in survival between the medical and surgical patients. Multivariable analyses identified shock, visceral ischemia, arch involvement, aortic rupture,

stroke, previous sternotomy, pulmonary disease, and female gender as significant, independent predictors of overall death. In the Baylor series, actuarial survival after surgical repair of type B dissections was 76%, 54%, and 35% at 1 year, 5 years, and 10 years, respectively; independent determinants of late death were earlier year of operation, older age, severe symptoms, higher New York Heart Association functional class, extent of aorta replaced, type of procedure, residual aneurysmal disease, and postoperative complications.⁹⁵ More recent mid-term data from IRAD indicated that 3-year survival of patients discharged alive from the hospital was 78% for those treated medically, 82% with surgical treatment, and 76% with endovascular techniques ($P = NS$).¹⁰⁰ Predictors of late death were female gender, prior aortic aneurysm, history of atherosclerosis, in-hospital renal failure, in-hospital pleural effusion, and hypotension or shock during hospitalization.

Congestive heart failure, renal failure, stroke, and cancer accounted for almost 50% of the late deaths in patients with acute type B dissections in the Stanford series, emphasizing the importance of patient-specific factors in determining their long-term prognosis.¹ Rupture of a contiguous or remote segment of the aorta was responsible for 16% of late deaths in this Stanford series, compared with 29% of late deaths in the 20-year long-term follow-up study from DeBakey and coworkers.²¹ This sobering figure should be amenable to improvement if more diligent patient follow-up imaging surveillance and medical care are provided.

Aortic Reintervention

The actuarial freedom from late aortic reoperation and late aortic-related complications after treatment of acute type B dissection in the overall Stanford experience is illustrated in Figure 71-5B-D. Surprisingly, there was no significant difference in reoperation rate between patients treated medically and those treated surgically.¹ After 5 years, reoperation was necessary in 14% of the medical group and 13% of the surgical patients; at 10 years, reoperation was necessary in 17% of both groups. The only independent predictor of late aortic reoperation was Marfan syndrome, underscoring the fragility of the dissected aorta in these patients. In Crawford's 1990 study analyzing a 33-year experience with surgical management of aortic dissection (type A or B, acute or chronic), 22% of patients required aortic reoperation 10 years later and 88% were free from aortic rupture.⁹⁵ Residual aneurysmal disease, no cardioplegia (probably indicative of improved surgical techniques over time), and preoperative New York Heart Association functional class were the determinants of late aortic rupture; a higher likelihood of reoperation was significantly linked to earlier year of operation, previous proximal aortic procedure, aortic cross-clamp time, and more limited surgical procedures that have been abandoned (e.g., primary repair, aortoplasty, patch repair). In a retrospective analysis of 101 patients with uncomplicated acute type B dissections treated medically, Marui and colleagues^{70,101} from Japan reported that patent false lumen, aortic diameter exceeding 40 mm, and fusiform dilation of the proximal

FIGURE 71-5 **A**, Actuarial survival for all patients with acute type B dissections subdivided according to initial treatment method. There was no statistically significant difference in survival between those treated surgically and those treated medically. For perspective, this graph also portrays the survival curve for the age- and gender-matched U.S. population; this indicates that only 35% of patients this age can be expected to be alive 20 years later. **B**, Actuarial freedom from late aortic reoperation (defined as surgical procedures related to the aorta or to complications of the dissection) subdivided according to initial treatment. There was no statistically significant difference between treatment modalities. **C**, Freedom from reoperation for all patients, expressed in actual (or observed cumulative frequency) terms. **D**, Actuarial freedom from late aortic-related complications or death for all 189 patients. (From Umaña JP, Lai DT, Mitchell RS, et al: Is medical therapy still the optimal treatment strategy for patients with acute type B aortic dissections? *J Thorac Cardiovasc Surg* 124:896–910, 2002.)

descending aorta were predictors of late aortic events; these authors recommended that such patients be considered for early surgical intervention.

FOLLOW-UP

In patients with acute type B aortic dissection, whether they were initially treated medically or surgically, an early predischarge CTA or MRI scan is mandatory to rule out early complications and to serve as a baseline reference. During the first few weeks, these patients require close outpatient medical care; attention should be focused on

blood pressure control and cerebral, cardiac, and renal function.^{7,29} Periodic imaging studies of the entire thoracic and abdominal aorta are essential indefinitely to detect aortic complications, such as aneurysmal degeneration of the downstream aortic false lumen, before rupture or death. Attention should also be paid to the patency of the false lumen because it is now known that partial thrombosis of the false lumen (as opposed to patent false lumen or complete thrombosis of the false lumen) is associated with higher mortality than in patients with a patent false lumen.¹⁰² Our protocol calls for the interval between imaging studies to be lengthened gradually from 3 to 6 months during the first year after the

acute event if no worrisome interval changes are detected, then annually thereafter. Lifelong rigorous blood pressure control and negative inotropic therapy are also critically important. In DeBakey and colleagues' 1982 report,²¹ late aneurysmal formation occurred in 45% of patients with poor blood pressure control, compared with 17% of those with well-controlled hypertension. A combination of conventional antihypertensive agents and negative inotropic medications is usually required and needs to be continued indefinitely, even in normotensive patients.⁷⁹ Improvements in the follow-up management of these patients are still needed because mortality rates after discharge from the hospital are still higher than expected (almost one in four patients dying within the first 3 years), irrespective of initial treatment modality.^{1,100}

SUMMARY

The development of thoracic endovascular aortic repair (TEVAR) has dramatically revolutionized the field of cardiovascular surgery. Since Parodi's first description of an intraluminal stent graft device for the treatment of abdominal aortic aneurysms,¹ endovascular device technology has rapidly evolved to treat the multiple pathologies seen in the thoracic aorta. In 1994, Dake first reported the initial Stanford experience with 13 patients undergoing endovascular therapy of descending thoracic aortic aneurysms.² Since then, indications involving off-label use have expanded to include the treatment of aortic dissections, traumatic transections, penetrating atherosclerotic ulcers (PAUs), and intramural hematoma (IMH). Currently, there are four stent graft devices approved by the U.S. Food and Drug Administration (FDA) for the treatment of descending thoracic aortic aneurysms. Questions and concerns remain regarding the appropriate timing, indication of intervention, and durability of

this fast-evolving technology. TEVAR has gained worldwide acceptance in the treatment of pathologies of the descending thoracic aorta (DTA). In the span of a decade, TEVAR has gained on-label FDA approval for the treatment of thoracic aortic aneurysm, PAU, blunt thoracic aortic injury, and type B aortic dissection. This change attests to the rapid evolution and adoption of this technology in treating thoracic aortic pathology.

As TEVAR technology evolves, recent reports have shed light on the utility of endovascular technology in treating ascending aortic and aortic arch pathology—primarily ascending aortic dissection, ascending aorta IMH/PAU, and aortic arch aneurysms in poor open surgical candidates. With improving technology, it is likely that in the future TEVAR will have a defined role in the treatment of ascending aortic and aortic arch pathology. Currently, it has become the gold standard for treatment of descending thoracic aortic pathologies.

DESCENDING THORACIC AORTIC ANEURYSMS

Natural History and Indications for Intervention

Thoracic aortic aneurysms are abnormal dilation of the aorta, characterized by elastin fragmentation and fibrosis, resulting in medial degeneration of the aortic wall.³ These age-related changes likely result in the reduction of aortic integrity and strength. As the population ages, the incidence of thoracic aortic aneurysms appears to be increasing. In a recent Swedish study examining the national health care registry from 1987 to 2002, the incidence of thoracic aortic pathology rose by 52% in men and by 28% in women, reaching 16.3 per 100,000 per year and 9.1 per 100,000 per year, respectively. In the same study, the annual incidence of operations performed on the thoracic aorta increased from 0.8 per 100,000 per year in 1987 to 5.6 per 100,000 per year in 2002 for an overall sevenfold increase. In women, the increase was 15-fold, from 0.2 per 100,000 per year in 1987 to 3.0 per 100,000 per year in 2002.⁴

The natural history of thoracoabdominal aortic aneurysms has been examined in large single-institutional series. Characterized by slow growth over time, aortic aneurysmal degeneration is an indolent pathologic process of aortic dilation leading to potential rupture or dissection. The human aorta grows generally at a rate of about 0.07 cm per year in the ascending aorta, and 0.19 cm per year in the descending thoracoabdominal aorta.⁵ If dissection is present, the thoracoabdominal aorta may grow at a slightly faster rate of 0.28 cm per year.^{6,7}

The major risk in thoracic aortic aneurysms pertains to the catastrophic events of rupture or dissection. The risk of rupture or dissection as a function of maximum aortic diameter has been examined in multiple studies. Clouse and coworkers examined the Olmstead County database and demonstrated that in patients with a maximum aortic diameter measuring 4.0 to 5.9 cm, the risk of rupture was 16% over a period of 5 years. When the maximum aortic diameter is greater than 6.0 cm, the risk of rupture exceeds 30% over the same period of 5 years.⁸ The Yale group have also identified “hinge points” of maximum aortic diameter that represent significant increases in the risk for rupture. In the ascending aorta, this “hinge point” appears to be at 6 cm, with a risk of rupture or dissection at 34% over the lifetime of the patients. In the DTA, the “hinge point” appears to be at 7 cm, with a 43% risk of rupture or dissection.⁶ The annual risk of rupture or dissection as a function of maximum aortic diameter has also been examined. Davies and coauthors⁵ demonstrated that in patients with a maximum aortic diameter of less than 6.0 cm, the yearly rates of rupture, dissection, or death, is less than 8%; however, the annual risk of rupture, dissection, or death dramatically increases to 15.6% when the maximum aortic diameter is greater than or equal to 6.0 cm.

General recommendation for the indication for surgical intervention has been made based on these large

institutional population studies. The decision to intervene surgically must be based on a balance between the risk of surgery or intervention (in the case of TEVAR) versus the risk of rupture or dissection with medical management. The general consensus for conventional open repair is to intervene surgically at a diameter of 5.5 cm for the ascending aorta and a diameter of 6.5 cm for the DTA. Certainly, patients with significant family history of aortic disease or connective tissue disorder such as Marfan syndrome may warrant intervention at a lower threshold of aortic diameter. Furthermore, for patients with symptomatic aneurysmal disease, urgent surgical intervention is recommended regardless of size, because symptoms are an early indicator of impending rupture.

In the era of TEVAR, the perceived lower rates of morbidity and mortality have urged the question: Should the threshold for intervention in the DTA be lowered? With a mortality rate of less than 5% with TEVAR in most centers of excellence,⁹⁻¹² most patients with a descending thoracic aortic diameter greater than 5.5 cm may be considered for endovascular repair (Fig. 72-1). However, the final decision to intervene must be based on previously established surgical dictum: the risk of rupture must outweigh the risk of surgery, regardless of approach.

Device Development

Since the early devices were first described by the Stanford group in 1994,² TEVAR devices have undergone multiple modifications and clinical trials. There are four thoracic endoprotheses currently approved for the treatment of descending thoracic aortic aneurysms. Second- and third-generation devices, as well as disease-specific devices, are currently being investigated.

Gore TAG

The Gore TAG thoracic endoprosthesis (W.L. Gore, Inc., Flagstaff, AZ) was approved by the FDA in March 2005 for the treatment of descending thoracic aortic aneurysms. The first device to be approved, the Gore TAG, is a self-expanding polytetrafluoroethylene endograft comprised of nitinol support. Concern over fracture of the longitudinal support wire led to the revision of the

FIGURE 72-1 ■ Angiogram demonstrating endovascular treatment of thoracic aortic aneurysm.

original Gore device to its current Gore TAG endoprosthesis. Unique to this device system is the introducer sheath, which enables the delivery of multiple devices and minimizes traumatic injury to the femoral access vessels. The introducer sheath ranges from an inner diameter of 20 Fr to 24 Fr depending on the size of the Gore TAG devices required for treatment. The Gore TAG endoprosthesis ranges from a minimal diameter of 26 mm to a maximum diameter of 40 mm, with lengths ranging from a minimum of 10 cm to a maximum of 20 cm (Fig. 72-2). The mechanism of deployment involves release of the endograft from a center to peripheral fashion. Thus, precise deployment of the proximal and distal landing zones may be difficult.

In August 2011, Gore Conformable-TAG (C-TAG) device received FDA approval. The C-TAG has essentially replaced the older-generation TAG device. It provides greater flexibility and conformability, with a broad, oversizing window (6%-33%), and is available in straight and tapered forms. The C-TAG is available in a smaller-diameter range than the TAG device (21 mm) and can be placed using an 18 Fr (inner diameter) delivery system. C-TAG is now FDA approved for use in thoracic aortic aneurysm disease, PAU, blunt thoracic aortic injury, and complicated type B dissection.

Medtronic Talent and Valiant Thoracic Endoprosthesis

The Talent Device. Recently approved in June 2008 by the FDA for the treatment of descending thoracic aortic aneurysms, the Talent device is a preloaded stent graft incorporated into a CoilTrac delivery system. It is a stent graft composed of a polyester graft (Dacron) sewn to a self-expanding nitinol wireframe skeleton. Radiopaque markers are sewn to the graft material to aid in visualization during fluoroscopy. The CoilTrac delivery system is

a sheathless, push-rod-based delivery system. Preloaded onto an inner catheter, the Talent device is deployed by pulling back an outer catheter, allowing the device to self-expand and contour to the aorta. A balloon may be used to ensure proper apposition of the graft to the aneurysmal aorta after deployment.

The Talent device is designed as a modular system. Forty-seven different configurations ranging from a diameter of 22 to 46 mm and cover lengths from 112 to 116 mm are available. To accommodate the size differences often found between the proximal and distal portions of the aorta in thoracic aneurysms, tapered grafts are available for better aneurysmal conformability and prevention of junctional endoleaks. Four configuration categories are available: proximal main, proximal extension, distal main, and distal extension (Fig. 72-3). The proximal configurations and the distal extension are offered with a bare-spring design (Free-Flo design). The bare-spring design allows for placement of the device crossing the arch vessels proximally and the celiac artery distally for suprasubclavian and infraceliac fixation, respectively.

The Valiant Device. The Valiant device is designed based on the experience with the Talent device. Similar to the Talent device, the Valiant device is also a preloaded stent graft made of the same polyester graft built onto a self-expanding nitinol skeleton. Modification has been made to improve trackability, conformability, and deployment of the Valiant device. First, device lengths have been increased to a maximum of 230 mm (130 mm for Talent). Because the device is a sheathless system, each piece requires an individual deployment through the access vessel, resulting in repeated exchange in the artery. Longer lengths have been designed to minimize device exchange

FIGURE 72-2 ■ The Gore TAG thoracic endoprosthesis. (Courtesy W.L. Gore, Inc., Flagstaff, AZ.)

FIGURE 72-3 ■ The Medtronic Talent thoracic endoprosthesis (Medtronic Vascular, Santa Clara, CA).

during deployment. Second, the connecting bar has been removed in the Valiant device for improved conformability, especially in the arch. Third, the number of bare springs at the proximal and distal ends of the device has been increased from 5 to 8 in the Valiant device to improve circumferential force distribution and fixation along the aorta wall. Finally, the Valiant device is introduced in a new delivery system, the Xcelerant Delivery System. First available to physicians in the United States for the AneuRx AAA device, the Xcelerant Delivery System has been modified for the Valiant Device to provide a more comfortable deployment mechanism of the device, especially in tortuous anatomy of the distal arch and thoracic aorta. As opposed to a simple pullback unsheathing mechanism, the deployment of the Xcelerant Delivery System includes a gearing, ratchet-like mechanism in the handle to allow easy deployment. The amount of force required to deploy the device is reduced significantly without compromising the precision of the deployment.

Similar to the Talent device, The Valiant device is a modular design. Eighty-eight different configurations ranging from a diameter of 22 to 46 mm and cover lengths from 110 to 200 mm are available in the Valiant device. Four configurations categories are available: proximal FreeFlo straight component, proximal closed-web straight component, proximal closed-web tapered component, and distal bare-spring straight component. The proximal FreeFlo straight component is designed for the most proximal deployment zone, because the bare springs are designed to allow precise and crossing deployment of the arch vessels. In addition, it is designed as the first piece to be deployed.

In 2012, results of the VALOR II trial were reported for the use of the Valiant endoprosthesis for DTA aneurysm repair.¹³ The pivotal trial was conducted at 24 U.S. sites, assessing 30-day and 12-month outcomes. At 30 days, there were rates of 3.1% mortality, 38.1% major adverse events, 0.6% paraplegia, and 2.5% stroke. At 12 months, aneurysm-related mortality was 4%, with a stent migration rate of 2.9% and an endoleak rate of 13%.

Cook Zenith TX2 Thoracic Endoprosthesis. Recently approved in 2008 by the FDA, the Cook Zenith TX2 thoracic endoprosthesis (Cook, Inc., Bloomington, IN) is designed as a modular system with a specific proximal and distal configuration (Fig. 72-4). The graft consists of stainless steel Z-stents with full-thickness polyester fabric. Similar to the Medtronic delivery system, the Zenith TX2 system does not require a delivery sheath, and it is introduced as a preloaded catheter with triggers. The device sheath has a hydrophilic coating and sizes range from 18 to 22 Fr, depending on the diameter of the endoprosthesis. The diameter of the endoprosthesis ranges from 22 to 42 mm and lengths from 120 mm to 207 mm. The two components are designed to be deployed from a proximal to distal direction, and tapered devices are available.

Deployment of the TX2 is achieved through a trigger system to ensure a controlled deployment. Flushed at the proximal end with barbs to prevent migration and endoleak, the device is deployed by an unsheathing mechanism. To minimize the “wind sock” effect during

FIGURE 72-4 ■ The Cook ZenithTX2 thoracic endoprosthesis (Cook, Inc., Bloomington, IN).

deployment (thus distal migration), the proximal barb component of the device is not released until the graft is deployed and the trigger released. The distal component is deployed in a similar mechanism. However, in addition to barbs, the distal component also has bare springs at its caudal portion. Proximal and distal extensions are available if additional coverage is necessary.

Bolton Relay Prosthesis. The Bolton Relay graft (Bolton Medical, Inc., Sunrise, FL) is the latest new company to receive FDA approval (in 2012) for TEVAR treatment of DTA aneurysmal pathology. The Relay system features a four-step sheath delivery system for modular delivery (outer diameter 22-26 Fr), with graft lengths ranging from 100 to 250 mm in straight and tapered forms; graft diameters range from 22 to 46 mm, with proximal and distal components. Proximal grafts are available in two types—Relay uncovered graft and Relay NBS covered graft. They feature S-bar (spiral support strut) technology that runs longitudinally along the stent graft, enabling improved support to the entire structure. The Relay system enables proximal capture of stent graft for precise placement, along with a secondary sealing and fixation zone that provides an extra sealing independent of proximal sealing.

Anatomic and Technical Considerations

Anatomic requirements and key technical considerations for successful TEVAR revolve around answering the question of what makes a patient a suitable anatomical candidate for a thoracic aortic stent graft. Initial assessment of a stent graft candidate begins with an extensive preoperative workup and evaluation. Key points of the history and physical examination should include a detailed

neurologic and cardiovascular examination. Distal vascular pulses and preoperative neurologic deficiencies must be documented. Previous abdominal, pelvic, and inguinal surgeries should be noted, because these procedures may demand an alternate access route.

Access

Safe vascular access for thoracic aortic device deployment is the key to thoracic aortic stent grafting. The majority of the morbidity and mortality is a direct result of arterial access complications.^{9,10,12} Extensive preoperative planning with appropriate imaging is mandatory. The “gold standard” for preoperative evaluation is a computed tomography (CT) angiogram that includes the thorax, abdomen, pelvis, and femoral arteries. Fine-cut helical CT scanning with at minimum 3-mm slices is ideal (Fig. 72-5). In patients who cannot receive a CT with contrast, magnetic resonance angiography is an acceptable substitution.

All the thoracic endovascular devices take a long time to reach the descending aorta, are of large caliber to contain the thoracic aortic endoluminal graft, and are relatively stiff to allow “pushability” through the iliofemoral access points and through the abdominal aorta. The management of the delivery of the thoracic aortic stent graft is often the most challenging aspect of the case. Delivery systems of the three currently FDA-approved thoracic endoprostheses will require arterial access size of a minimum of 7.5 to 8.0 mm. Creation of a conduit to the femoral or iliac artery may be necessary to achieve adequate access. Not only the size of the arterial vessels, but also the anatomy of the iliofemoral and abdominal aorta, must be considered when planning the access route. Excessive tortuosity and atherosclerosis with occlusive disease may provide barriers to safe delivery of the endograft. In approximately 20% of patients, retroperitoneal access to the common iliac arteries will be required owing to issues of femoral or external iliac artery size and/or tortuosity.¹⁴

FIGURE 72-5 ■ Computed tomographic angiography of a descending thoracic aortic aneurysm.

Careful review of preoperative studies will indicate which patients will have difficult access. Patients with atherosclerotic occlusive iliac disease may be treated with standard endovascular techniques of balloon angioplasty to reduce the obstruction. Iliac stents should be avoided because of the potential interference of these stents with the thoracic aortic access devices. These procedures on the access vessels should be carried out at least 6 weeks before thoracic aortic stent grafting to allow healing of the iliac arteries post-angioplasty and manipulation. At the completion of the thoracic aortic endografting, iliac stents may be placed if appropriate.

Access to the retroperitoneum allows several options for safe device deployment. The common iliac artery may be used for device deployment. An open surgical conduit can be constructed to allow an end-to-end anastomosis or a side-to-side anastomosis. A 10-mm conduit of synthetic Dacron is commonly used and allows ample size for insertion of all necessary devices. The conduit may be brought through a separate counterincision in the groin to allow better angulation of the relatively long and stiff deployment devices. At the conclusion of the procedure, these conduits may be used to revascularize distal obstructions if needed.

Alternatively, the retroperitoneal iliac vessels, or even the distal aorta, may be accessed using direct sheath insertion. A double purse string of 4-0 Tyron is used to secure the vessel and provide hemostasis with the application of two sets of tourniquets. Direct needle puncture of the artery is followed by dilation and insertion of the device. At completion, the device is removed and the purse string sutures are tied down. Excessive tortuosity of the iliofemoral arteries requires adaptive strategies. The use of external manual manipulation provides a simple method of straightening some of the tortuosity of the aorta and iliac arteries. During fluoroscopy the operator hand can provide gentle force to the tortuous arterial segment to allow straightening and subsequent endovascular access.

In cases of iliac artery tortuosity, advanced endovascular techniques may aid in straightening these segments. The use of stiff wires or buddy wire techniques can provide some degree of straightening of the diseased arteries. In severe cases of tortuosity, brachiofemoral access may be required to perform “body flossing” with an appropriately stiff wire. Typically, a 5 Fr sheath with a long catheter is placed into the aortic arch and then into the descending aorta. A long, stiff wire, such as a 450-cm SS Guidewire (Boston Scientific, Natick, MA), is guided from the brachial artery and retrieved through the femoral artery. Gentle traction on both the brachial and femoral sites will straighten out the tortuosity. Of note, a long catheter must be placed through the brachial artery into the aorta to prevent excessive trauma by the stiff wire along the arch and innominate vessels.

At the completion of the deployment and ballooning of the thoracic stent graft, the entire route of access must be carefully examined to ensure that there has been no injury. The stiff guidewire that was used to position the thoracic endograft should be left in place as the sheaths and remaining endovascular materials are removed. A smaller sheath should be reinserted and a diagnostic

FIGURE 72-6 ■ Iliac artery avulsion after removal of an endovascular delivery system.

aortoiliac arteriogram should be performed to evaluate for thrombus, dissection, or complete avulsion.

The removal of the large sheath, especially when inserted with some force and manipulation, is a particularly dangerous period when injury may occur. There have been numerous reports of successful thoracic endografting with a sheath removed with a complete iliac artery avulsed and attached (Fig. 72-6). At the time of recognition, a stiff wire through this injured artery may be life-saving and allow insertion of an occluding balloon proximally to allow control of a potentially life-threatening bleed. In addition, both blood pressure and heart rate should be carefully monitored during removal and completion of the endovascular procedure for signs of an occult injury.

Landing Zones

The proximal aorta is divided into landing zones as illustrated in Figure 72-7. Unless revascularization is performed, proximal landing in zones 0 and 1 is unacceptable because of the necessary occlusion of the left common carotid artery in zone 1 and the innominate artery in zone 0. Proximal landing in zone 2 is commonly used with either partial or total occlusion of the left subclavian artery. Zone 3 landing is dependent on the exact anatomical neck at the arch. Proximal landing in zone 3 can lead to angulation of the graft, which provides inadequate sealing of the proximal graft along the lesser arch and “bird beaking” or “stove piping” graft placement, which results in a high incidence of Type II endoleaks. Zone 4 landing is usually straightforward because of the lack of angulation and distance from the arch vessels.

The proximal and distal landing zones must be of an appropriate diameter to allow for stent grafting with available devices. In general, devices should be oversized over the diameter of the landing zone between 15% and 20%, depending on the presenting aortic pathology. As has been discussed, the proximal landing zone of the aorta must be carefully examined on preoperative imaging workup. The goal is to create a good “seal” of 15 to 20 mm between the graft and the aortic wall on a disease-free, nontapered, nonangulated portion of the aorta.

FIGURE 72-7 ■ Classification of landing zones in thoracic aortic endovascular repair. (From Mitchell RS, Ishimaru S, Ehrlich MP, et al: First International Summit on Thoracic Aortic Endografting: roundtable on thoracic aortic dissection as an indication for endografting. *J Endovasc Ther* 9[Suppl 2]:1198–105, 2002.)

There should be adequate length of the proximal landing zone, minimal angulation, minimal tortuosity, and minimal calcification. Angulation of the aortic arch is acceptable if the inner radius is greater than 35 mm and the outer radius is greater than 70 mm. These parameters allow adequate conformation of the aortic stent graft to the arch.

Because zone 2 is often the site of best proximal landing to avoid excessive angulation and tortuosity, the management of the left subclavian artery requires preoperative planning. Some of the possible complications of covering the left subclavian artery include vertebrobasilar artery insufficiency or stroke, left arm ischemia, or ischemia of the heart in patients with a previous left internal mammary artery to left anterior descending coronary artery bypass graft. An evaluation of the right vertebral artery and the adequacy of the circle of Willis is crucial when planning to cover the left subclavian artery. In patients with inadequate collaterals through the circle of Willis, stenotic right vertebral artery, or a dominant left vertebral artery, strong consideration should be made to bypass the left subclavian artery before covering. One option is to transpose the left subclavian artery to the left common carotid artery with oversewing of the proximal left subclavian artery. A second option is to bypass from the left common carotid artery to the left subclavian artery. Either surgical ligation of the proximal

left subclavian at the time of bypass or staged-coil embolization of the proximal left subclavian artery at the time of graft delivery may be used. Bypass of the left subclavian artery may be preferable because it avoids any mediastinal dissection and there is no interruption of antegrade flow to the vertebral artery or internal mammary artery branch vessels.¹⁵

Evaluation of the distal landing zone also requires careful preoperative workup. The distal landing zone should again have 15 to 20 mm of normal aorta with minimal calcification, angulation, and tapering. The celiac artery is the first distal branch vessel that must be avoided. Therefore, the length of the aortic graft must be correctly planned. Enough graft length should cover the aortic pathology while avoiding excessive coverage of the DTA. The goal is to preserve the distal vertebral artery branches and perfusion to the spinal cord.

Results

Multicenter Clinical Trials

The Gore TAG endoprosthesis was approved as a result of the phase 2 U.S. multicenter trial comparing the Gore TAG endoprosthesis (W.L. Gore) to an open surgical control group in the treatment of descending thoracic aortic aneurysms.⁹ Between September 1999 and May 2001, 140 patients with descending thoracic aortic aneurysms were enrolled from 17 sites in the United States. All patients were required to have adequate landing zones of at least 2 cm length of nonaneurysmal aorta distal to the left carotid and proximal to the celiac axis. At the same centers, the open surgical control cohort enrolled 94 patients. Forty-four patients were concurrent controls and 50 were historically and retrospectively acquired by selecting the most recent surgical patients in reverse chronological order.

In the endograft group, statistically significant improvement was seen in the 30-day mortality, incidence of postoperative respiratory failure, renal failure, spinal cord ischemia (SCI), mean intensive care unit, and hospital stay. Thirty-day mortality was 2.1% and 11.7% in the Gore TAG group and the open surgical control group, respectively. SCI was 2.9% in the Gore TAG group versus 13.8% in the control group. However, peripheral vascular complications were significantly higher in the endograft group (14% vs. 4% control group).⁹

The mean duration of follow-up was 25.8 months in the endograft group and 24.9 months in the open control group. Kaplan-Meier 2-year survival was similar between the two groups (78% endograft group vs. 76% control). The incidence of endoleak at 1-year and 2-year follow-up was 6% (6/103) and 9% (7/80), respectively. There were no cases of aneurysm rupture in either group. At 2-year follow up, 45% of the endograft group had aneurysmal regression of 5 mm or greater, 42% had no change, and 13% had aneurysmal progression of 5 mm or greater.⁹ At 5-year follow-up, all-cause mortality remains similar between the two groups (68% endograft group vs. 67% control). Aneurysm-related mortality was lower in the endograft group (2.8%) when compared with the control group (11.7%).¹⁶

The Vascular Talent Thoracic Stent Graft System for the Treatment of Thoracic Aortic Aneurysms (VALOR) trial led to the approval of the Talent endoprosthesis for the treatment of thoracic aortic aneurysms. The Medtronic VALOR trial was a prospective, multicenter, nonrandomized, observational trial evaluating the use of the Medtronic Talent thoracic stent graft system in the treatment of thoracic aortic pathology. The study was conducted from 2003 to 2005 and involved 38 sites. A total of 195 patients were enrolled, with 189 patients identified as retrospective open surgical controls. In the Talent group, the 30-day mortality was 2.1%, with an incidence of paraplegia of 1.5% and stroke of 3.6%. One-year mortality was 16.1% with aneurysm-related mortality of 3.1%. When compared with the surgical control group, the Talent arm demonstrated statistically superior outcome in perioperative mortality (2% vs. 8%, $P < 0.01$), 30-day major adverse events (41% vs. 84.4%, $P < 0.001$), and 12-month aneurysm-related mortality (3.1% vs. 11.6%, $P < 0.002$). In 2012, results were reported from the VALOR II trial, which assessed the Valiant stent graft system for degenerative disease of the DTA.¹³ It was a prospective, nonrandomized, pivotal trial conducted at 24 U.S. sites enrolling 160 patients. The perioperative mortality rate was 3.1%, stroke rate was 2.5%, and paraplegia/paraparesis rate was 2.5%. At 12 months, endoleak rate was 13%, with 4% aneurysm-related mortality. The Valiant device was statistically noninferior to the Talent graft.

Published in 2008, the international controlled clinical trial of the TX2 device is a nonrandomized, controlled, multicenter, international trial comparing the treatment of thoracic aortic aneurysm with the TX2 endoprosthesis versus open repair. Enrollment began in March 2004 and was completed by July 2006. From 42 institutions, a total of 160 patients were enrolled in the endovascular group and 70 patients in the open group. The 30-day survival rate was noninferior for the TX2 group when compared with the control group (98.1% vs. 94.3%). The 30-day cumulative major morbidity scores were significantly lower in the TX2 group when compared with the control group (1.3 vs. 2.9). Although not statistically significant, the incidence of neurologic complications trended in favor of endovascular repair. The incidence of stroke in the TX2 group was 2.5% at 30 days compared with 8.6% in the control group. The incidence of paraplegia in the TX2 group was 1.3% versus 5.7% in the control group. At 12 months' follow-up, aneurysmal growth was seen in 7.1%, endoleak in 3.9%, and device migration in 2.8%. One-year survival estimated from all-cause mortality was similar between the TX2 group (91.6%) and the control group (85.5%). The 1-year survival estimate from aneurysm-related mortality was also similar between the TX2 group (94.2%) and the open surgical control group (88.2%).¹²

In September 2012, the Bolton Relay thoracic stent with Plus delivery system received FDA approval. Current on-label indications for Relay stent graft use in the United States include thoracic aortic aneurysm and PAU. In a study by the RESTORE investigators¹⁷ (multicenter, prospective European trial), outcomes for Relay stent graft treatment of a variety of thoracic aortic pathologies

(aneurysm dissection, PAU, IMH, pseudoaneurysm) were assessed in 304 enrolled patients. Thirty-day mortality was 7.2%, and perioperative stroke and paraplegia rates were 1.6% and 2%, respectively. Two-year freedom from device-related mortality was 95.9%. In a more recent study looking at subgroup analysis in patients treated for traumatic aortic injury, the clinical success with Relay graft was achieved in all 40 cases. Thirty-day mortality was 2.5%, and actuarial 2-year survival was 93.7%.

European Registries

Multicenter experience with TEVAR has also been accumulating in Europe. The Talent Thoracic Registry (TTR) is a database collected from seven European centers. All patients in the registry underwent TEVAR with the Medtronic Talent endoprosthesis between November 1996 and March 2004. The registry involved 457 patients, and the spectrum of pathologies comprised 180 (39.4%) thoracic aortic dissections, 137 (29.9%) atherosclerotic aneurysms, 14 (3%) pseudoaneurysms, 29 (6.35%) penetrating ulcers, 12 (2.6%) IMHs, and 85 (18%) traumatic aneurysms.¹¹ The in-hospital mortality rate was 5%. Technical failure defined as failure to complete an intended stent graft deployment was 2.2%, with a conversion rate to surgery of 2.2%. The in-hospital complication rate was 12.7% and included stroke (3.7%), paraplegia (1.7%), and vascular access issues (3.3%). The mean follow-up was 24 months with 11 late aneurysm-related deaths. Kaplan-Meier overall survival estimate at 1 year was 90.97% and at 5 years was 77.49%. Freedom from reintervention was 92.45% and 70.0% at 1 and 5 years, respectively.¹¹

The results from the European Collaborators on Stent Graft Techniques for Thoracic Aortic Aneurysm and Dissection Repair (EUROSTAR) and United Kingdom Thoracic Endograft Registry were recently published in 2004.¹⁸ This registry included a total of 443 patients (EUROSTAR 340, UK 103) with thoracic aneurysms or dissections in the thoracic aorta who underwent endovascular repair between 1997 and 2003. The patients were recruited from 62 European countries, and the devices deployed included Medtronic Talent, Gore Excluder, and Zenith or Endofit (Endomed). Technical success was achieved in 87% of patients with degenerative aneurysms and 89% with aortic dissection. The 30-day mortality rate in the entire group was 9.3%, with 30-day mortality of 5.3% in the elective aneurysmal group. In the aneurysmal group, neurologic complications included paraplegia (4.0%) and stroke (2.8%). At one-year follow-up, cumulative survival in the degenerative aneurysm group was 80.3%, with 2 (2.1%) aneurysmal-related deaths. The incidence of endoleak at one year was 4.2%, with a reintervention rate of 5.2%.

Complications

Vascular Access

The most common complication associated with TEVAR has been related to vascular access because of the requirement of large-diameter devices. In most series, the access

complication rates can be as much as 22.5%.⁹⁻¹² Complications include vessel disruption, dissection, frank rupture, pseudoaneurysm, arteriovenous fistula, thrombosis, and distal embolic events. Extensive preoperative planning and decisive intraoperative bailout maneuvers are necessary to minimize potentially lethal vascular access complications.

Endoleak

Endoleak is defined as the presence of persistent blood flow into the aneurysm sac after the deployment of an endovascular aortic stent graft device. In earlier series, TEVAR has been associated with an endoleak incidence of 9.6% to 25.9%.⁹⁻¹² Table 72-1 demonstrates the classification of endoleaks associated with endovascular repair of aortic aneurysms.

The presence and the potential development of endoleak during follow-up mandate life-long aortic surveillance with computed tomographic angiography (CTA). Proximal and distal endoleaks (type I) are most commonly the result of inadequate or poor landing zones. Type III, or junctional, endoleaks are likely the result of inadequate overlap of devices, aneurysmal sac expansion, or aortic lengthening over time. In contrast to type II or type IV endoleaks, types I and III endoleaks will likely require further reintervention, either at the time of the primary endografting or at late reintervention during follow-up. Types II and IV endoleaks require strict follow-up and likely will not need further intervention unless symptoms or complications develop.

We recently reviewed the impact of endoleak on our TEVAR experience.¹⁹ Over a 6-year retrospective review period, 105 patients underwent TEVAR with either the Medtronic Talent or the Gore TAG device. Of these 105 patients, 69 patients had sufficient radiographic follow-up to be evaluated. The mean follow-up period was 17.3 months. The total incidence of endoleak was 29%. In these patients, types I, II, and III endoleaks were seen in 40%, 35%, and 20%, respectively. Predictors of endoleaks include more extensive and larger aneurysms at the time of TEVAR, male sex, length of aortic treatment, and increasing number of devices used. The majority of types I and III endoleaks were treated successfully with reintervention, and significant aneurysmal sac regression was seen on follow-up. In contrast, most type II endoleaks were successfully managed with conservative therapy and strict surveillance.

Neurologic Complications

Neurologic complications associated with TEVAR fall within two major areas: stroke and SCI. Stroke is a devastating complication of TEVAR, with an incidence of approximately 3% to 9%.⁹⁻¹² The risks for stroke in TEVAR are likely multifactorial. Arch atheroma burden and embolic events are likely significant risk factors, because endovascular placement of thoracic aortic stent graft often requires multiple wire manipulations in the aortic arch. These manipulations may contribute to increased stroke risk by producing distal emboli. Other risk factors for stroke include history of previous stroke

TABLE 72-1 Classification Scheme for Endoleak and Endotension

Description	
Endoleaks* (Type)	Source of Perigraft Flow
I	Attachment site leaks [†]
A	Proximal end of endograft
B	Distal end of endograft
C	Iliac occluder (plug)
II	Branch leaks [‡] (without attachment site connection)
A	Simple or to-and-fro (from only 1 patent branch)
B	Complex or flow-through (with 2 or more patent branches)
III	Graft defect [§]
A	Junctional leak or modular disconnect
B	Fabric disruption (midgraft hole)
	Minor (<2 mm; e.g., suture holes)
	Major (≥2 mm)
IV	Graft wall (fabric) porosity (<30 days after graft placement)
Endotension [§] (Type)	
A	With no endoleak
B	With sealed endoleak (virtual endoleak)
C	With type I or type III leak
D	With type II leak

*Endoleaks also can be classified on the basis of the time of first detection as: perioperative, within 24 hours of EVAR; early, 1 to 90 days after EVAR; and late, after 90 days. In addition, they can be described as primary, from time of EVAR; secondary, appearing only after not being present at time of EVAR; and delayed, occurring after prior negative computed tomographic scan results. Endoleaks also can be described as persistent, transient or sealed, recurrent, treated successfully, or treated unsuccessfully. Endoleaks and endotension may be associated with AAA enlargement, stability, or shrinkage.

[†]Some type I and type III leaks also may have patent branches opening from AAA sac and providing outflow for leak.

[‡]From lumbar, inferior mesenteric, hypogastric, renal, or other arteries.

[§]Endotension (strict definition) is defined here as increased intrasac pressure after EVAR without visualized endoleak on delayed-contrast computed tomographic scans. In the generic sense, endotension is any elevation of intrasac pressure and occurs with type I, type III, and most type II leaks and endotension in the strict sense.

^{||}Detectable only on opening aneurysm sac.

and grade V atheroma of the aortic arch, and coverage of the left subclavian artery.²⁰

SCI resulting in paraplegia is an equally devastating complication of thoracic aortic surgery. Endovascular stent graft repair of isolated descending thoracic aortic aneurysms has a reported SCI frequency that ranges from 3.6% to 12.0%, with approximately two-thirds of these cases being permanent deficits.²¹ Endovascular therapy offers several potential advantages in reducing the risk of SCI. These advantages include the avoidance of an aortic crossclamp, fewer episodes of hypotension, less bleeding, and an earlier emergence from general anesthesia to allow detection and treatment of a neurologic deficit.

Conversely, stent grafting may have the disadvantages of requiring more extensive aortic coverage to allow adequate sealing between endoluminal graft and aorta, the inability to reimplant intercostal arteries, and injury to iliofemoral vessels that may provide flow to the anterior spinal artery through the hypogastric and pelvic vascular plexus.

Identified risk factors for SCI after thoracic aortic stent grafting include previous abdominal aortic aneurysm repair (AAA), long segment of thoracic aortic stent graft, mobile atheroma, vascular injury, hemorrhage, and hypotension.^{21–23} The mechanisms that contribute to SCI are multifactorial. The risk of SCI in patients with previous AAA repair may be explained by the destruction of pelvic and hypogastric arterial collateral to the anterior spinal artery. Extended graft coverage, especially in the levels of T6 to T12, compromises the vertebral levels that supply the anterior spinal artery. Hypotension and hemorrhage contribute by decreasing the perfusion pressure to the spinal cord.

Techniques to reduce the risk of SCI include using lumbar cerebrospinal fluid drains and neurocerebral monitoring. The use of a lumbar cerebrospinal fluid drain has been shown in numerous studies to decrease the risk of SCI in open surgical thoracoabdominal aortic aneurysm repairs and endovascular thoracic aortic aneurysm and dissection stent graft repair.^{24,25} The use of neurophysiologic monitoring has been traditionally used to detect intraoperative spinal cord ischemic changes and to allow changes in perfusion management to reverse insults. The use of neurophysiologic monitoring in endovascular treatment of the thoracic aorta has been reported to also allow early detection and intervention to augment spinal cord perfusion pressure to decrease the risk.²⁶

AORTIC DISSECTIONS

Although TEVAR for elective repair of descending thoracic aortic aneurysm has been performed worldwide with increasing frequency, it is the potential role of TEVAR in acute thoracic aortic pathologies such as aortic dissections and traumatic aortic injury that has garnered increasing investigation. Through recent surgical advances, morbidity and mortality with conventional surgical repair have been reduced to acceptable perioperative complication rates. However, mortality for emergent thoracic aortic pathologies remains significant. The minimally invasive nature of TEVAR potentially offers a surgical alternative for this group of high-risk patients. The emerging role of TEVAR in acute aortic dissection will be discussed next.

Natural History and Indications for Intervention

In 1650, Sennertus was the first to describe the process of a tear in the intima of the aorta. However, the term *dissection* was not described until 1802, by Manoir. Until this century, aortic dissection was a postmortem diagnosis. Over the centuries, numerous surgical techniques for aortic dissection have been described with limited clinical

success. It was not until the 1950s, with the development of cardiopulmonary bypass, that surgical repair of aortic dissection became a clinical success.²⁷ Over the last 50 years, techniques to repair ascending aortic dissection have been refined, and surgical intervention has become the preferable therapeutic option.

Classification

Aortic dissection is classified based on the location of the primary tear site and dissection flap. Two classification systems currently exist. The DeBakey system classifies dissection based on the location of the dissection and its extension. Type I dissection begins in the ascending aorta and may involve most of the remaining distal aorta, whereas type II dissection involves only the ascending aorta with no extension beyond the aortic arch. Type III dissection begins distal to the left subclavian artery and involves the proximal thoracic aorta (type IIIa) or further to the iliac arteries (type IIIb). In contrast, the Stanford system classifies dissections into two types. Dissection involving the ascending aorta regardless of its extension is classified as type A. Type B dissection begins distal to the left subclavian artery and involves only the DTA.

Aortic dissection has also been classified based on its timing of presentation. Acute dissection has traditionally been classified as presentation within the first two weeks of the initial symptoms, whereas subacute dissection has been classified as presentation between two weeks and two months. Patients with dissections who present after two months after the initial symptoms are classified as chronic dissection.

Indications for Intervention

Surgical treatment of acute proximal aortic dissection (Stanford type A) has been established as the standard of care, demonstrating significant improvement in survival when compared with medical management. In all but the highest-risk patients, the presence of a dissection in the ascending aorta is in itself an indication for surgery. Current series have demonstrated surgical mortality rates ranging from 9% to 25%.²⁸⁻³⁵ In contrast, medical therapy is associated with a 1-month mortality rate as high as 60%.³⁶ Experience with endovascular repair of acute type A aortic dissection remains limited.³⁷⁻³⁹ Because of these limitations in the current technology, widespread clinical use has not been adopted. However, future development may result in the application of endovascular technique in the ascending aorta.

The management of acute type B aortic dissection remains less well defined. Traditionally, acute type B dissection without complications (i.e., rupture, malperfusion, hemodynamic instability) has been managed successfully with anti-impulse medical therapy, demonstrating low morbidity and mortality rates. According to the International Registry of Acute Aortic Dissection (IRAD),³⁶ uncomplicated type B dissection treated with medical therapy is associated with a mortality rate of 10.7%. In contrast, emergent open surgical repair has historically been associated with significantly higher morbidity and mortality.³⁶

Although medical therapy of uncomplicated type B dissections is associated with good early outcomes, long-term outcome and survival of patients with type B dissection remain disappointing. As much as 20% of patients with type B dissection develop complications (i.e., rupture, malperfusion) requiring surgical intervention.³⁶ Actuarial survival for all patients was 71%, 60%, 35%, and 17%, at 1, 5, 10, and 15 years, respectively, regardless of medical versus surgical therapy.⁴⁰ In most series, 10-year survival regardless of the mode of therapy is between 40% and 50%.⁴⁰⁻⁴³ Furthermore, there appears to be no difference in the freedom from reoperation and freedom from aortic-related complications between the medical and surgical treatment.⁴⁰

The poor long-term outcome of uncomplicated type B dissection is a result of the predisposition of these patients to develop aneurysmal dilation of the thoracoabdominal aorta.⁴⁴ Contemporary series have reported the incidence to be upwards of 80% over a five-year period.^{45,46} Subgroup populations of patients with acute type B aortic dissections also appear to be at risk of poor long-term survival. Predictors of increased long-term mortality include persistent patency with partial thrombosis of the false lumen,^{44,47-49} false lumen diameter greater than 22 mm at the time of initial presentation,⁵⁰ and total aortic diameter greater than 40 mm.⁵¹

Patients with acute type B aortic dissections who present with life-threatening complications including rupture or malperfusion syndrome remain a challenging group to manage. Historically, conventional open surgical therapy in this group of patients has been associated with significant morbidity and mortality, ranging from 30% to 50%.⁵²⁻⁵⁴ Despite improvement in surgical technique, in-hospital mortality remains significant. In the most recent IRAD review, in-hospital mortality in patients undergoing surgical repair of type B aortic dissection was 29.3%. For patients presenting with malperfusion and rupture, the in-hospital mortality rates were 27.8% and 62.5%, respectively.⁵⁴

An alternative surgical option for both acute uncomplicated and complicated type B aortic dissection remains desirable. Many have examined the role of endovascular technique in the acute type B aortic dissection. In uncomplicated cases, the role of TEVAR remains unclear. For patients with complicated type B dissection, the role of TEVAR has emerged as the gold standard, replacing open surgery as the first-line treatment for complicated type B dissection.

Anatomic and Technical Considerations

Endovascular therapy for acute aortic dissection is technically demanding. Some have argued that the current technology is not ideal and that devices designed specifically for dissection are needed.^{55,56} Nonetheless, we emphasize that the complexity involved with endovascular therapy for aortic dissection requires an algorithmic approach that must begin at the primary tear site. Wire access in the true lumen cannot be overemphasized, because deployment of thoracic stent graft devices in the false lumen will have catastrophic consequences. When confirmation of wire access in the true lumen is

needed, intravascular ultrasound has proven to be a valuable tool.

The fundamental principles of endovascular treatment of aortic dissection have major conceptual differences from aneurysmal pathology. The primary goal is coverage of the primary tear site, thus expanding the true lumen and initiating thrombosis and obliteration of the false lumen (Fig. 72-8). Often, the tear site is located in close proximity to the left subclavian artery and coverage is necessary. Despite successful thoracic stent graft therapy, persistent patency of the false lumen may occur because of complex reentry points in the distal thoracoabdominal aorta. In contrast to aneurysmal disease, sizing of the endograft devices should be conservative. The endograft devices should be minimally oversized relative to the diameter of the dissected aorta, generally at most 10%. Aggressive ballooning of the landing zones should also be discouraged.

Particularly in cases with malperfusion syndrome (because the goal of therapy is to restore distal perfusion and correct end-organ ischemia), false-lumen patency may persist despite thoracic aortic endografting. The true lumen may continue to be compressed, thereby resulting in continued malperfusion and end-organ ischemia. Called the PETTICOAT (Provisional Extension to Induce Complete Attachment) concept,⁵⁷ the principle refers to an algorithmic evaluation and treatment of the thoracoabdominal aorta in type B aortic dissection. After coverage of the primary tear site, the status of the true lumen is assessed. If persistent malperfusion is present, deployment of an additional distal device is performed. This evaluation and treatment algorithm is repeated with each adjunct device until distal malperfusion is corrected. In patients with persistent visceral malperfusion despite coverage of the primary tear site, TEVAR in the distal thoracic aorta with adjunct celiac, superior mesenteric artery, or renal bare metal stents should be considered. Subsequently, persistent lower extremity malperfusion may require infrarenal aortic and iliofemoral adjunct procedures including bare metal stents.

For dissections complicated by rupture, coverage of the primary tear site is equally essential. However, the site of rupture must also be addressed with TEVAR. Because of the extent of the dissection and the potential for perfusion of the false lumen through distal complex reentry sites, often the coverage of the entire thoracic aorta from the left subclavian artery to the celiac artery is required. Failure to recognize this concept may result in continued hemorrhage from the rupture site and potentially death.

Results

Uncomplicated Type B Dissection

The rationale for the use of TEVAR in type B dissections is based on the concept that the obliteration, or thrombosis, of the false lumen with an endograft may result in positive aortic remodeling and thus improvement in long-term outcome and survival. Closure of the primary tear site of a type B dissection should promote decompression of the false lumen, with subsequent reestablishment and stabilization of the true lumen of the aorta.

The first use of TEVAR in type B dissections was reported by Dake and coworkers in 1999. The series involved 19 patients undergoing TEVAR for acute aortic dissections; 15 patients had the diagnosis of acute type B aortic dissections. Complete thrombosis of the thoracic aortic false lumen was achieved in 15 patients (79%), with a 30-day mortality rate of 16%. In the follow-up period of 13 months, there was no death.⁵⁸

Many other investigators have reported favorable short-term results with complete and partial obliteration of the false lumen in type B dissections, demonstrating stabilization of the descending aorta in as much as 75% of patients.⁵⁹⁻⁶⁵ Kusagawa and coworkers reported a series of 49 patients with type B dissections (32 acute, 17 chronic). The mean follow-up period ranged from 4 months to 6 years. In the acute dissection group, the average false lumen decreased from an average of 16 mm

FIGURE 72-8 ■ Angiogram demonstrating endovascular treatment of acute type B aortic dissection. **A**, Positioning of the thoracic endovascular aortic repair (TEVAR) graft in the true lumen of the proximal descending thoracic aorta (DTA) is shown predeployment. **B**, Aortic arch and DTA angiogram post-TEVAR deployment in the true lumen shows loss of filling in the false lumen.

to 3 mm at 2 years after treatment. In 76% of the patients, the false lumen of the thoracic aorta completely disappeared after 2 years. The results were less dramatic in the chronic group.⁵⁹

Dialetto and coworkers reported a series of 56 patients with type B dissections treated either medically ($n = 28$) or with aortic stent grafts ($n = 28$). Follow-up ranged from 1 to 61 months, with 100% follow-up. In-hospital mortality was 10.7% with no incidence of spinal cord ischemia. Follow-up CT scans demonstrated complete thrombosis of the false lumen in 75% of patients treated with TEVAR compared with only 10.7% of patients in the medically treated group. Aneurysmal dilation of the descending aorta was seen in only 3.5% of patients treated with TEVAR compared with 28.5% of patients in the medically treated group.⁶⁰

Eggebrecht and coworkers recently reported a meta-analysis of TEVAR for patients with type B dissections. Thirty-nine studies were included, with a total of 609 patients. The mean follow-up period was 19.5 months. The mean procedural success rate was 98.2%, with a complication rate of 11.1%. The rate of neurologic complications was 2.9%, with stroke at 1.9% and paraplegia at 0.8%. Overall, complications were statistically higher in patients with acute type B dissection (21.7%) when compared with chronic type B dissection (9.1%). The 30-day mortality rate in the acute and chronic dissection groups were 9.8% and 3.2%, respectively. False-lumen thrombosis was seen in 75.5% of patients. Late surgical conversion was required in 2.5% of patients. Endovascular reintervention with TEVAR was necessary in 4.6% of patients. Overall survival by Kaplan-Meier analysis was 90.6%, 89.9%, and 88.8% at 6 months, 1 year, and 2 years, respectively.⁵⁵

The role of TEVAR in acute uncomplicated type B aortic dissection was recently examined in the INvestigation of STent grafts in patients with type B Aortic Dissection (INSTEAD) trial. It was a multicenter, prospective, randomized trial in Europe designed to compare the outcomes of uncomplicated type B dissections treated by (1) TEVAR (Medtronic Talent device) adjunctive to anti-impulse therapy or (2) anti-impulse therapy alone. The study period was 2 years with the primary outcome measure as all-cause mortality. Secondary outcomes included conversions to TEVAR or surgery, false lumen thrombosis, cardiovascular morbidity, rate of aortic dilation, quality of life, and length of intensive care unit and hospital stay. At 1 year, there was no difference in all-cause mortality between the medical (3%) versus the TEVAR (10%) group.⁶⁶ Long-term results of the INSTEAD trial were recently published.⁶⁷ Compared with optimal medical management, TEVAR showed an improved risk of all-cause mortality (6.9% vs. 19.3%, $P = 0.13$) and aorta-specific mortality (6.9% vs. 19.3%, $P = 0.04$) at 5 years. Elective TEVAR rendered improved false-lumen thrombosis in 90.6% of cases ($P < 0.001$).

Recently, outcomes with the management of acute uncomplicated type B dissection with best medical therapy versus best medical therapy with Gore TAG stent graft was assessed. This was a prospective randomized trial (ADSORB trial).⁶⁸ Sixty-one patients were randomized, of which 80% had DeBakey type IIIB dissection.

Although there was no mortality difference at 30 days and 1 year, there was a significantly improved false-lumen thrombosis rate (57% vs. 3%) and false-lumen-diameter reduction ($P < 0.001$) in the best medical therapy + Gore TAG arm. The study concluded that acute uncomplicated type B dissection can be safely treated with stent grafting, with improved aortic remodeling.

In summary, the benefit of TEVAR in acute uncomplicated type B aortic dissection is becoming increasingly evident. Results of TEVAR for the treatment of type B dissection appear promising, demonstrating early evidence of false-lumen thrombosis and aortic remodeling. However, further long-term follow-up data from future trials will be needed before definitive conclusions can be made regarding the impact on aortic remodeling and survival benefit.

Complicated Type B Dissection

Endovascular therapy in the treatment of complicated type B dissections in the acute setting has emerged as a viable surgical alternative, and in some institutions, TEVAR has become the preferred therapy of choice. Duebener and coworkers reported a series of 10 patients with complicated acute type B dissections treated with TEVAR. The mean interval to treatment from the time of diagnosis was 11 hours. Indications for TEVAR were rupture ($n = 2$), malperfusion ($n = 5$), rapid aortic expansion ($n = 1$), and refractory pain ($n = 2$). The primary tear site was covered in 90% of patients, and the early mortality was 20% ($n = 2$). The causes of death in the two patients were aortic disruption distal to the stent graft and hemorrhagic shock after surgical fenestration of the abdominal aorta for persistent malperfusion. The duration of follow-up ranged from 1 to 38 months.⁶⁹

Doss and coworkers reported their experience of 54 patients undergoing emergent surgical management of thoracic aortic diseases, with 28 patients undergoing conventional open surgical technique and 26 patients undergoing TEVAR. The mean age of the patients ranged from 28 to 83 years. Of the 54 patients, the indication for intervention was perforated type B dissection in 14 patients. The mortality rate was 17.8% in the conventional surgical group versus 3.8% in the TEVAR group. Paraplegia rates were 3.6% and 0% in the conventional surgical and the TEVAR groups, respectively.⁷⁰ The same investigators reported their more recent experience with emergent endovascular treatment of acutely perforated type B dissections. In a series of 11 patients over a 10-month period, 7 patients were treated for ruptured aortic aneurysms and 4 for acutely perforated type B dissections. The average interval from diagnosis to treatment was 28 hours. Technical failure (i.e., access failure) occurred in 2 patients. At a mean follow-up of 12 months, there were no cases of paraplegia, stent migration, or endoleaks.⁷¹

Nienaber and coworkers⁷² reported their experience of 11 patients undergoing emergency TEVAR for acute type B dissections complicated by contained ruptures. Emergency TEVAR was successful with no morbidity and stent-graft-related complications. At a mean follow-up of 15 months, there was no mortality. This was

a statistically significant improvement compared with a historic-matched control group of patients undergoing conventional surgical therapy (death, $n = 4$).⁷²

At the University of Pennsylvania, we reviewed our experience with TEVAR for the treatment of acute type B aortic dissection complicated by rupture or malperfusion.⁷³ In our series from 2004 to 2007, 35 patients with acute type B aortic dissection were treated with TEVAR with a technical success rate of 97.1%. The indications for surgery were rupture in 18 patients and malperfusion in 17 patients. Malperfusion involved the mesenteric and renal vasculature in 5 patients, the lower extremity in 3 patients, and both in 9 patients. In addition to thoracic endograft devices, adjunct stent therapy including infrarenal aortic stents, iliofemoral stents, and celiac/mesenteric stents was required in 12 (34.3%) patients. The rate of renal failure (2.8%), CVA (2.8%), permanent spinal cord ischemia (2.8%), vascular access complications (14.2%), and 30-day mortality (2.8%) compare favorably with conventional open repair. Overall one-year survival was 93.4%. The recent IRAD database demonstrates that conventional open repair for acute type B aortic dissection in the current era is still associated with a significant risk of cerebrovascular accident (9.0%), paraplegia (4.5%), visceral ischemia/infarction (6.8%), and acute renal failure (18.3%), all of which were correlated with postoperative death. The overall in-hospital mortality rate was 29.3%, and for patients undergoing surgery within 48 hours, the in-hospital mortality rate was 39.2%.⁵⁴ The dramatic difference in morbidity and mortality between TEVAR and conventional open repair suggests that TEVAR is an effective surgical alternative and supports a new surgical paradigm for the treatment of acute complicated type B aortic dissection. At our institution, TEVAR has emerged as the surgical therapy of choice for the management of acute complicated type B aortic dissection.

PENETRATING ATHEROSCLEROTIC ULCER, INTRAMURAL HEMATOMA, AND BLUNT THORACIC AORTIC INJURY

Historically, PAU with IMH in the DTA has been managed medically. The behavior and clinical management of PAU and IMH in the DTA is not well defined and remains a clinical challenge. Furthermore, the natural history of PAU and IMH remains unclear.⁷⁴⁻⁷⁶ Cho and coworkers⁷⁷ recently reviewed the Mayo Clinic experience with PAU of the DTA over a 25-year period. From 1977 to 2002, 105 patients with PAU of the DTA with ($n = 85$) and without ($n = 20$) IMH were included in the study. The medical group included 76 patients and the surgical group included 29 patients. Thirty-day mortality in the medical group was 4% versus 21% in the surgery group ($P < 0.5$). Defined as conversion to surgery or death, failure of medical therapy was predicted by the presence of rupture at presentation and the era of treatment (before 1990). Aortic diameter, ulcer, or extent of hematoma were not risk factors for medical therapy failure or death.⁷⁷

The introduction of TEVAR has prompted investigators to examine the role of this new technology in descending thoracic aortic PAU and IMH. Jin and coworkers⁷⁸ reported their experience with TEVAR for PAU in the DTA. In their series of 14 patients, the majority of patients was symptomatic and was treated emergently. Endoleaks were present in two patients at completion angiography. With a mean follow-up period of 17.2 months, coverage of PAU was achieved in all patients, with complete resorption of IMH in 2 patients. One patient died of rupture of pseudoaneurysm at one month after surgery. Other investigators have also reported small series of endovascular aortic stent graft therapy for PAU and IMH.⁷⁸⁻⁸¹ Technical success with good short-term follow-up has been demonstrated with low mortality.

In summary, TEVAR for PAU and IMH in the DTA is promising. Endovascular therapy for complicated or symptomatic PAU appears to be indicated. However, more evidence and long-term follow-up are needed to arrive at definitive conclusions. Currently, the TX2, Valiant, and Relay devices have approved on-label indications for PAU treatment in the United States.

Blunt thoracic aortic injury is associated with high mortality, with only 10% of patients arriving to a hospital alive, of which up to 50% die within 24 hours. Endovascular repair of blunt thoracic aortic injury has gained increasing acceptance as the treatment of choice over open surgery. The C-TAG and Valiant endograft devices have received on-label indications by the FDA for the treatment of this condition.

AORTIC ARCH/ASCENDING AORTIC PATHOLOGIES

The introduction of TEVAR has provided an alternative surgical option in patients thought to be at prohibitively high risk for conventional open aortic arch or ascending aortic repair, although the use of endovascular technology in ascending aorta and aortic arch is through off-label use only.

Aortic Arch Endovascular Repair

The arch hybrid repair is essentially a landing zone “0” endovascular repair of the aortic arch and it is guided by two fundamental concepts: (1) brachiocephalic bypass, or revascularization of the great vessels; and (2) construction of optimal proximal and distal landing zones for TEVAR. The arch hybrid repair is especially appealing in patients who are poor candidates for prolonged periods of cardiopulmonary bypass or circulatory arrest—that is, older patients and those with significant comorbidities.

Landing Zones

The principle of anatomic landing zone selection is similar in arch hybrid cases to DTA stent grafting. The hybrid arch concept is an extension of the TEVAR proximal landing zone scheme. Hybrid arch procedures are typically performed with the proximal landing zone in Z0. Therefore, the arch hybrid concept necessitates a

FIGURE 72-9 ■ Arch hybrid classification is shown.

brachiocephalic revascularization procedure to preserve flow through the great vessels.

The hybrid arch repair classification is based on aortic arch aneurysm anatomy and proximal and distal landing zone feasibility. The scheme divides aortic arch aneurysms into three types (Fig. 72-9). The type I arch hybrid is typically done with a classic arch aneurysm, where the ascending and descending thoracic aortas are not aneurysmal or dissected. This anatomy has favorable proximal Z0 and distal Z3/Z4 landing zones, respectively. A type I arch hybrid repair only requires great vessel revascularization with either concomitant antegrade TEVAR stenting or delayed retrograde TEVAR from the iliofemoral vasculature. A type II arch hybrid is an ideal approach in an arch aneurysm without a good Z0 proximal landing zone but has a good distal landing zone in the DTA. Therefore, a type II repair necessitates an open surgical Z0 landing zone reconstruction for proper deployment and seal of the proximal stent graft. Type III arch hybrid repair can be used for even more complex aortopathies such as the mega-aorta syndrome. In this case, the native aorta does not have good proximal or distal landing zones for stent graft deployment. Therefore, a type III repair necessitates an open surgical reconstruction of proximal aorta and arch as a total arch replacement with elephant trunk for stent-graft landing in the DTA. It is important to note that in progression from a type I to a type III arch hybrid repair, the circulatory management options become increasingly complex and therefore must be tailored to patient status and anatomy.

Outcomes

To date there have been no randomized trials evaluating the use of hybrid techniques for the treatment of aortic arch pathology. Several groups have published their single-institution hybrid experience with an in-hospital mortality rate of 0% to 13%, and a permanent stroke rate between 0% and 8%. The incidence of paraplegia was between 0% and 24%.⁸²

Two groups reported their outcomes with type I hybrid arch repair. Both groups report a 0% stroke rate

and one in-hospital death in a total group of 30 patients.^{83,84} Shimamura and colleagues⁸³ reviewed 126 type II hybrids and reported a total stroke rate of 5.6%, a paraplegia rate of 2.3%, and an in-hospital mortality rate of 3.2%. The largest series of type III hybrids, done by Kawaharada and associates,⁸⁴ demonstrated a stroke rate of 3.2%, a paraplegia rate of 0%, and an in-hospital mortality rate of 6.4%.⁸⁴ Although the data reported by these studies are encouraging, they remain limited by the small number of patients treated in their retrospective analysis.

A meta-analysis of 15 studies reporting outcomes for arch hybrid procedures revealed an overall 30-day mortality rate of 8.3%, a stroke rate of 4.4%, a paraplegia rate of 3.9%, and an endoleak rate of 9.2%. A total of 463 patients were included in this analysis.⁸⁵

Ascending Aorta Endovascular Repair

TEVAR is not currently indicated for ascending aortic pathology; however, several centers have described their anecdotal experiences with endografting in the ascending aorta.^{37,86-88} To date, there have been no clinical trials or large series describing outcomes with TEVAR in the ascending aorta. Kolvenbach and colleagues⁸⁹ have described their experience with ascending aorta TEVAR in 11 patients. They report a stroke rate, endoleak rate, and mortality rate of 9%, with a combined mortality and morbidity of 18%. Technical success was achieved in 91% of patients. They concluded that a significant number of their complications were a result of using an endograft that was not designed for unique anatomy of the ascending aorta.

In January 2012, Metcalf and colleagues⁸⁸ described the first case of ascending aorta TEVAR with an endograft designed specifically for the ascending aorta. Their group implanted a Zenith Ascending Dissection device (Cook Medical, Bjaeverskov, Denmark) in a 68-year-old man with an acute type A dissection.⁸⁸ The patient made an uneventful recovery. Currently, several devices are under development for use in clinical trials evaluating the use of TEVAR in the ascending aorta.

SUMMARY

TEVAR has emerged as a viable surgical alternative to the treatment of thoracic aortic pathology. For the treatment of aneurysmal disease, perioperative morbidity and mortality is favorable when compared with conventional open techniques. Midterm outcome and long-term follow-up demonstrate durable results with long-term survival comparable with conventional open repair. Perhaps it is in the setting of acute aortic syndromes that TEVAR may potentially have its greatest impact. Historically associated with significant morbidity and mortality, acute aortic syndromes including traumatic transection, rupture, pseudoaneurysm, and dissection remain major clinical challenges. Although TEVAR is technically more challenging, its results have been favorable in the treatment of acute aortic dissections.

Endarterectomy

SUMMARY

Frequently, and in a variety of clinical settings, cardiovascular surgeons encounter occlusive disease involving the branches arising from the aortic arch. As a result of the increasing average life expectancy of human beings, there is a growing subset of older patients who are found to have brachiocephalic occlusive disease incidentally during preoperative evaluation for more routine cardiac surgery. In addition, the widespread use of the internal thoracic

artery (ITA) as the conduit of choice for patients with surgically correctable coronary artery disease has created a subset of patients who, postoperatively, are susceptible to coronary ischemia from occlusive disease involving the subclavian vessels, which produces coronary-subclavian steal syndrome.

Although atherosclerosis is the most common cause of brachiocephalic occlusive disease, other, less common causes of aortic branch occlusive disease, such as Takayasu arteritis and radiation-induced arteritis, can also manifest as occlusion of the aortic arch branch vessels that occasionally requires surgical intervention. Regardless of the cause of intrathoracic brachiocephalic occlusive

*Disclosure: Dr. Coselli serves as a consultant for Vascutek Ltd., a subsidiary of Terumo Corporation.

disease, advancements in diagnostic imaging, technical improvements in end-organ protection, the development of endovascular techniques, strategic anesthetic management, and a better understanding of critical care all have enabled cardiovascular surgeons to perform a wide variety of procedures to treat patients with this problem with low operative risk.

Concomitant occlusive disease involving coronary and carotid arteries can pose particular challenges for cardiovascular surgeons, and the ideal treatment strategy for these combined lesions remains controversial. Treatment algorithms for concomitant coronary and carotid occlusive disease have recently expanded with the advent of endovascular techniques. Current strategies for treating patients with this problem include synchronous revascularization, staged procedures, hybrid approaches using endovascular devices, and medical treatment.

OCCLUSIVE DISEASE INVOLVING THE BRACHIOCEPHALIC ARTERIES

Pathophysiology

Atherosclerosis of the aortic arch has been recognized recently as a significant contributor to and an independent predictor of embolic stroke and generalized atherosclerotic disease, and it is the most common cause of intrathoracic brachiocephalic occlusive disease.¹ In addition to its well-known associations with cigarette smoking, peripheral arterial occlusive disease, dyslipidemia, hypertension, male sex, and diabetes mellitus, atheroma has also been associated with elevated levels of fibrinogen and homocysteine.^{2,3} Aortic arch atheroma, first seen early in the patient's adult life, is characterized by gradually increasing severity.⁴ The progression of aortic arch atheroma to brachiocephalic occlusive disease is influenced directly by the presence of aggravating risk factors.

Two important pathologic sequelae directly related to aortic arch plaques are atheroembolism and thromboembolism.⁵ Within the aging aortic arch, a variety of pathophysiologic processes occur: these include calcification, the destruction of smooth muscle and elastic fibers (including the loss of internal elastic lamina), the formation of thrombi, and most importantly, the deposition of atherosclerotic plaques.⁶ The vast majority of occlusive lesions of branching vessels of the arch and of the upper-extremity arterial branches are atherosclerotic in origin, and disease often involves multiple vessels.⁷⁻⁹ In addition, because of the irregular nature of these plaques, embolic phenomena resulting from thrombus deposits—composed of both platelets and fibrin—can occur in nearly a third of such patients. Thrombotic or thromboembolic events predominantly occur in patients with multifocal disease. Embolic phenomena owing to ostial disease of the aortic arch branches are uncommon. A cardiogenic source of embolism must be excluded before emboli can be conclusively attributed to arch branch disease.¹⁰

Inflammatory disorders, such as Takayasu arteritis or polymyalgia rheumatica, are among the less common causes of arch branch occlusive disease. The prototypic vasculitis syndrome that commonly leads to occlusive

disease of the thoracic aorta and its branches is Takayasu arteritis. This disease is characterized by immune-mediated destruction of the medial elastic fibers of the affected vessel, followed by scarring of the media and internal elastic lamina, which causes compensatory intimal proliferation. Takayasu arteritis remains an idiopathic large-vessel vasculitis that generally affects women of reproductive age and predominates in Asians; however, it has been reported in patients of all ethnicities.¹¹ Cardiac failure and cardiomegaly are usually secondary to hypertension and aortic valvular insufficiency. Approximately 60% of patients with Takayasu arteritis require some form of vascular intervention, most commonly involving the coronary arteries, followed by the carotid and upper-extremity arteries.

Additional disorders that can be causative include arteritis stemming from radioactive therapy (for malignancies of the neck or Hodgkin disease), traumatic injuries (e.g., penetrating missile injuries and blunt deceleration injuries), vasospastic disorders, thoracic outlet syndrome, and possibly connective tissue disorders. Radiation therapy can lead to stenosis of the brachiocephalic vessels and induce unpredictable atherosclerotic changes several years after treatment, ultimately resulting in embolic or diminished-flow phenomena.

Clinical Presentation

Clinical manifestations of brachiocephalic occlusive disease (Fig. 73-1) are predominately related to the degree of luminal encroachment in the primary vessel affected and the extent of collateral disease if multiple vascular beds are compromised. Stenosis of aortic arch branches can have direct ischemia-related consequences or lead to steal syndromes in which increases in blood flow to one region result in ischemia in another. Involvement of the innominate artery can lead to anterior, posterior, or combined cerebral symptoms, depending on the amount of collateral flow from the contralateral side via the circle of Willis and the extent of concomitant subclavian or common carotid artery (CCA) involvement. Isolated right-sided steal syndromes can occur, but only if the disease arises in the right subclavian artery and the innominate is relatively spared. In contrast, involvement of the left subclavian artery can result in either upper-extremity claudication or vertebral steal manifesting as vertebrobasilar symptoms, depending on the exact location of the stenotic lesion.

In general, the clinical presentation of patients with brachiocephalic occlusive disease involves either an acute embolic or a chronic stenotic event. Acute embolic symptoms tend to involve cerebral hemispheric events related to anterior circulation and, similar to carotid bifurcation disease, amaurosis fugax. Less often, emboli can affect the upper extremities, usually evidenced by cold or numb hands or fingers. Commonly, stenotic lesions reduce blood flow to upper extremities (and occasionally to lower extremities) and can result in subclavian steal syndrome. Exercise can induce ischemia and cause hand or arm cramping or fatigue (this process is also known as *claudication*); in time, these symptoms can progress to rest pain and possibly to tissue loss.

FIGURE 73-1 ■ Common symptoms of occlusive disease involving the brachiocephalic branches. Compromised flow or emboli from common carotid artery lesions can cause a variety of neurologic symptoms, including transient ischemic attacks (TIAs) and amaurosis fugax. Subclavian artery lesions can cause vertebral-basilar insufficiency (including vertebral-subclavian steal), cardiac complications (including angina, myocardial infarction [MI], and congestive heart failure [CHF]) caused by coronary-subclavian steal, and upper-extremity arterial insufficiency or microembolization. (From Takach TJ, Reul GJ Jr, Cooley DA, et al: Myocardial thievery: the coronary-subclavian steal syndrome. *Ann Thorac Surg* 81:386–392, 2006.)

Takayasu arteritis is associated with a broad spectrum of clinical presentations that range from a fairly indolent chronic course to an acute fulminant disease. The initial symptoms most commonly reported by patients are constitutional and include myalgia, arthralgia, and headaches. Vascular symptoms commonly include claudicatory symptoms, carotidynia, and pulseless extremity. The diffuse involvement of major branches of the aorta contributes to an overall diminution of peripheral pulses in these patients, which is why Takayasu arteritis is sometimes referred to as *pulseless disease*. The nonspecific nature of the initial presentation contributes to the delay in the diagnosis of most cases of Takayasu arteritis. The Ueno classification system categorizes the disease into four types according to the extent and location of involvement. Types 1 and 3 are characterized by a disease process that affects the aortic arch and its branches.¹² Stenosis and occlusion are typical of Takayasu arteritis, and the lesions can be either short and segmental or long and diffuse. De novo aneurysms are rare but have been reported in all major branches of the aortic arch.^{13,14} Most aneurysms

arise from sites of previous anastomoses or surgical repair.^{15,16}

The age at presentation for patients with radiation-induced disease primarily depends on the age at which they were exposed to radiation, and is often younger than for those with atherosclerotic occlusive disease. These patients have angiographically atypical lesions that appear diffuse, unlike the focal lesions typical of atherosclerosis.¹⁷ Presentation includes either embolic or flow-limiting symptoms.

Diagnostic Evaluation

Diagnostic imaging, performed after a detailed initial vascular and neurologic examination, plays an important role in determining the appropriate treatment for each patient. A thorough neurologic examination, even in patients with isolated upper-extremity ischemic symptoms, is essential, because such symptoms could potentially be a manifestation of a steal syndrome and concomitant disease elsewhere. Other critical components of a thorough physical examination include measuring the blood pressure in both arms (a systolic difference greater than 20 mm Hg usually suggests proximal occlusive disease) and conducting a detailed pulse examination of the subclavian artery distribution at several locations: the wrist (radial and ulnar arteries), the upper arm and elbow (brachial artery), the armpit (axillary artery), and in the supraclavicular fossa. An absent or weakened pulse found anywhere other than the supraclavicular fossa tends to indicate arterial occlusion. In addition, an Allen test should be performed because the absence of a blush in any section of the hand usually indicates an incomplete palmar arch. Palpation of the infraclavicular and supraclavicular fossae is helpful to identify a subclavian aneurysm or cervical rib. A bruit identified during auscultation of the subclavian artery may indicate thoracic outlet compression of the artery.

The diagnosis of Takayasu arteritis is usually suspected from the patient's history and clinical presentation, and it is supported by the findings of specific serologic tests, tests for inflammatory markers, and angiography.¹⁸ Angiographic studies show a characteristic pattern of stenosis, poststenotic dilation, aneurysm formation, and occlusion with collateral formation. These findings tend to be localized to the aorta and the proximal aspect of its branches.^{19,20} Total body arteriography is an important component of the diagnostic workup of these patients to characterize the full extent of the disease and to provide a baseline for future comparison, because these patients require frequent serial imaging and monitoring for the rest of their lives.

Conventional Imaging Modalities

Digital subtraction angiography offers the opportunity for immediate endovascular intervention if a problem is discovered. As with any intravascular manipulation and imaging technique, the risk of embolic stroke always exists, especially in patients with atherosclerotic disease and plaques.²¹ The development of high-resolution

computed tomographic angiography with reconstructive capabilities has allowed this modality to substitute for digital subtraction angiography in the assessment of the aortic arch branches in specific circumstances. Computed tomography (CT) and magnetic resonance imaging (MRI) provide valuable imaging for assessing the extent of brachiocephalic disease. Contrast-enhanced MRI with reconstruction provides information equivalent to that obtained from conventional CT angiography. Magnetic resonance angiography (MRA), in addition, can yield useful information about occluded vessels reconstituted via collaterals because the imaging process is not contrast dependent. In addition, MRA provides valuable information about factors that affect the risk of embolization and consequent stroke, including the size, extent, and composition of atherosclerotic lesions. We recommend obtaining a preoperative CT angiogram or MRA for all patients who undergo surgical intervention on the branches of the aortic arch; the images serve as a baseline for future comparisons and for assessing the progression of the disease. Lifelong postoperative surveillance imaging and follow-up is an essential component of the care of these patients.²²

Ultrasonography and Emerging Imaging Modalities

Transthoracic echocardiography, although reliable for assessing the ascending aorta, is not ideal for assessing the arch and its branches because of its shallow depth of penetration and because the overlying ribs obscure these vessels. Similarly, transesophageal echocardiography (TEE) is limited in its ability to image the branches of the aortic arch, primarily because of shadowing from the trachea.²³ Intravascular ultrasonography is an emerging technology that may be useful during endovascular interventions.

The advent of transesophageal magnetic coils has made it possible to perform transesophageal MRI (TEMRI).^{24,25} Although TEMRI allows multiplanar reconstruction and provides better quantification of the extent of aortic atherosclerosis, real-time imaging and assessment of plaque mobility are feasible only with the help of TEE. Nonetheless, TEMRI provides a better assessment of the circumferential extent of atherosclerotic involvement than TEE does, and it could become an important option for imaging the supra-aortic great vessels.

Anatomic Considerations in Operative Exposures of Brachiocephalic Vessels

A thorough knowledge of thoracic anatomy is invaluable for the successful exposure of the supra-aortic vessels, and operative success is heavily dependent on good exposure with appropriate proximal and distal control. A median sternotomy provides adequate exposure for all the major arch vessels, including, in most cases, the left subclavian artery. A mini upper sternotomy up to the third or fourth intercostal space provides good exposure for the mid to distal innominate artery. This is useful in situations in which the proximal innominate artery is free of disease

and the aorta does not require clamping for proximal control. A Rummel tourniquet can be used for proximal control in these cases; however, this approach can be challenging to use when innominate artery bypass is necessary or when multiple vessels must be addressed. A full sternotomy is preferred in these circumstances. Extending the median sternotomy incision along the anterior border of the right sternocleidomastoid muscle provides adequate exposure of the bifurcation of the innominate artery and the right CCA. The same incision can be extended over the upper border of the right clavicle if exposure of the more distal aspects of the right subclavian artery is required. The right sternoclavicular joint may need to be dislocated to enhance exposure. Extending the median sternotomy along the anterior border of the left sternocleidomastoid enhances exposure for the left CCA.

The posterior location of the left subclavian artery makes exposure more challenging. When a median sternotomy is performed, it may be necessary to extend the incision over the left clavicle and to dislocate the left sternoclavicular joint for adequate exposure of the intrathoracic course of the left subclavian artery. Isolated left subclavian artery disease can be approached easily via a left posterolateral thoracotomy incision through the fourth intercostal space.

Structures that can interfere with exposure, as well as conduit positioning, are the thymic remnant and the left brachiocephalic vein. The thymus can be split longitudinally or even resected to provide adequate exposure. The brachiocephalic vein can be mobilized as far laterally as necessary so that it may be retracted out of the way to provide better exposure of the proximal arch branches. Ligating the vessel is occasionally necessary to enhance exposure of the left subclavian artery and left CCA. Ligation usually has no significant consequences except for transient left upper-extremity venous congestion. Ligating the brachiocephalic vein is not usually required for bypass procedures; bypass grafts can generally be safely tunneled behind the vein. Attention should be paid to the course of the recurrent laryngeal nerves if the dissection is carried out far laterally into the right subclavian artery and when one is gaining proximal control of the left subclavian artery and the subjacent aorta. The phrenic nerve is vulnerable to injury along its course over the anterior scalene muscle when the sternotomy incisions are extended over the clavicle. In addition, excessive traction in these incisions could jeopardize the functional integrity of the brachial plexus, producing undesirable long-term sequelae.

Cerebral protection is of concern in any operative manipulation involving the innominate artery or the CCAs. During the preoperative evaluation, one should thoroughly ascertain the patient's vascular anatomy, including the patency and size of the vertebral arteries and the completeness of the circle of Willis. Caution should be exercised, as usual, during placement of the proximal clamp and selection of the site for the proximal anastomosis to avoid any area on the aorta with atherosclerotic involvement. Epiaortic ultrasound can be helpful in selecting an ideal clamp site. The robust collateral circulation of the cerebral vasculature allows safe clamping of the innominate artery or proximal CCAs, provided

there is no diffuse or multivessel involvement. Flow through the left CCA should be ensured while the innominate artery is clamped. Similarly, it may be prudent to monitor a right subclavian arterial line when the left CCA is intervened on to ensure that there is flow through the innominate system. Furthermore, it may be helpful to monitor estimated hemispheric perfusion by using near-infrared spectroscopy to perform transcranial oximetry during innominate or left CCA clamping. The strategy for cerebral protection is more complicated in patients with contralateral carotid occlusion or multivessel disease, which occasionally necessitates the use of intraoperative shunts to ensure cerebral protection.

Surprisingly, postoperative neurologic complications are rare, even in patients with multivessel disease. Unless multivessel disease involving one or both carotids is encountered, electroencephalographic monitoring or shunting is usually unnecessary. Cerebral protection is more challenging in patients with a bovine aortic arch configuration, in whom clamping the innominate artery is not an option because this would compromise blood flow through both CCAs; shunting or temporary bypass conduits are essential in this circumstance.

Treatment

In 1958, DeBakey and colleagues²⁶ reported a large series of cases that included a direct transthoracic repair of the supra-aortic trunks—a major feat at that time. Surgical treatment was further advanced by Crawford and coworkers²⁷ with the use of extra-anatomic bypass techniques,

which dramatically decreased the mortality associated with these operations from 22% to 5.6%. Currently, extra-anatomic bypass with synthetic grafts is the most common technique for treating these complex lesions (Fig. 73-2). The use of shunting for cerebral protection when necessary and the recognition of high-risk patients who are likely to benefit from cerebral protective measures have dramatically curtailed the adverse neurologic consequences associated with these procedures. Alternative techniques include direct endarterectomy, endovascular stenting, and transposition.²⁸ In general, direct surgical approaches, such as bypass techniques, are preferred for multivessel and long-segment disease, whereas endovascular techniques are preferred for isolated ostial disease or short-segment disease. Surgical intervention has reportedly produced survival rates of 98% and relieved symptoms in 94% of patients at a mean follow-up of 7.5 years. Crawford and associates²⁷ reported survival rates of 85% at 5 years, 58% at 10 years, and 25% at 15 years. Hybrid and endovascular approaches have been added recently to the surgeon's armamentarium, and they are gradually becoming the preferred treatment modalities for occlusive disease of the supra-aortic trunks, particularly for older patients with significant comorbidity.^{29,30}

Innominate Artery Occlusive Disease

Innominate artery disease is uncommon. It typically involves the ostium or the proximal aspect of the artery and extends along the posterior and lateral walls. Innominate artery occlusion accounts for only 4.7% of cases of

FIGURE 73-2 Options for open surgical reconstruction of the brachiocephalic branches include extra-anatomic bypass procedures (A-E), aorta-to-brachiocephalic artery bypass procedures (D, H-N), and endarterectomies (E-G). (From Takach TJ, Reul GJ Jr, Cooley DA, et al: Concomitant occlusive disease of the coronary arteries and great vessels. *Ann Thorac Surg* 65:79–84, 1998.)

extracranial cerebrovascular disease.³¹ In these cases, the innominate artery is seldom the only vessel requiring revascularization.³² Reul and colleagues³³ found that 60% of patients undergoing revascularization for innominate artery symptoms required intervention in at least one other vessel. Early studies of treatments for innominate atherosclerotic disease favored an extrathoracic approach because of the high morbidity and mortality rates associated with intrathoracic repair.²⁷ Advances in surgical technique and anesthesia, however, produced equivalent results of either extrathoracic or intrathoracic approaches.³⁴ Current clinical indications for treating symptomatic stenosis include transient ischemic attacks (TIAs), stroke, vertebrobasilar insufficiency, subclavian steal syndrome, and upper limb ischemia.

In patients with atheroembolic manifestations, direct operative treatment by excluding the embolic source is an essential element of the treatment strategy for symptom relief. Direct repair or bypass using the transthoracic approach is preferred because it produces less morbidity than using the extrathoracic approach, which is reserved for patients in whom transthoracic repair is contraindicated.^{35,36} Relative contraindications to intrathoracic revascularization include a heavily diseased or calcified arch, previous thoracic surgery, and advanced age or poor medical condition. Extra-anatomic bypass techniques can be used in cases of primary graft infection, in which one would consider routing the graft well away from the preferred primary route. When revascularization of isolated innominate artery disease is contemplated, two transthoracic options exist: endarterectomy and bypass. Recent advances in endovascular treatment also represent a viable treatment strategy.

Innominate Artery Endarterectomy. Endarterectomy for isolated branch disease is reported to have excellent results.³⁶ Relative contraindications include inability to clamp the innominate artery, severe arch atherosclerosis, proximal origin of the left CCA (including a common brachiocephalic trunk), and multivessel disease; a bypass procedure may be preferable in these cases. Whenever possible, endarterectomy should be avoided in patients with Takayasu disease or radiation arteritis, because the transmural inflammatory process complicates the creation of an endarterectomy plane. The endarterectomy proceeds as illustrated in Figure 73-3. Performing intraoperative epiaortic ultrasonography before clamping may be of benefit, because most of these patients have aortic arch atherosclerosis. The vessel can be closed primarily or by patch angioplasty if luminal narrowing is of concern. Long-segment endarterectomies reportedly have been accomplished by extending the arteriotomy or performing separate arteriotomies on the branch vessels.³⁴

Innominate Artery Bypass. Bypass grafting with synthetic prosthetic graft material has produced excellent results and has become the operative procedure of choice. Although the results are comparable to those of endarterectomy, the technical ease of the operation has led surgeons to favor the bypass approach. Bypass techniques are especially well suited for use in cases of Takayasu arteritis, radiation injury, and recurrent atherosclerotic disease.

During the early phases of the development of arterial replacement surgery, operative techniques involved resecting the primary vessel and then placing an interposition graft; this approach was associated with significant

FIGURE 73-3 ■ **A**, After the right common carotid and subclavian arteries are clamped, proximal control of the innominate artery is established with a partial occluding clamp placed on the aortic arch. A longitudinal arteriotomy is created to expose the lesion. **B**, A circumferential endarterectomy plane is developed in the middle of the media. **C**, The endarterectomy is tapered distally to an appropriate endpoint. The lesion is divided proximally (dashed line) near the origin of the innominate artery; if the plaque extends into the arch, the intima is secured with tacking sutures to prevent dissection. The arteriotomy can be closed primarily or with a patch. (From Mozes G, Gloviczki P, Huang Y: Atherosclerotic occlusive disease. In Coselli JS, LeMaire SA, editors: *Aortic arch surgery: principles, strategies and outcomes*. West Sussex, United Kingdom, 2008, Wiley-Blackwell, p 311. Copyright Mayo 2005.)

perioperative morbidity and mortality. The introduction of the bypass technique by Crawford and coworkers³⁷ eliminated unnecessary manipulation and dissection of the diseased native artery while allowing the restoration of antegrade flow in the affected territory. This strategy reduced postoperative morbidity rates and significantly improved results. Late graft patency and patient survival (in those without stroke) appear to be good. Berguer and colleagues³⁵ reported 10-year estimates of $88\% \pm 6\%$ and $81\% \pm 7\%$, respectively. Concomitant coronary artery disease significantly influences both early and late death rates.

As with endarterectomy, epiaortic ultrasound is often useful in selecting the site of the proximal anastomosis and aortic clamping. Typically, an 8- to 10-mm Dacron graft is used to construct the bypass. When there is multivessel disease, a bifurcated or branched graft can be used. If at all possible, the proximal anastomosis should be constructed toward the right lateral aspect of the ascending aorta to avoid potential compression from the sternum or mediastinal contents. As reported by Crawford and colleagues,³⁸ the potential complications of such compression include venous compression and tracheal compromise resulting in death. Care should be taken to construct the bevel with the appropriate orientation to prevent kinking of the graft. The distal anastomosis is constructed in an end-to-side fashion unless the innominate artery is suspected to be the source of embolic disease. In that situation, the surgeon should consider excluding the diseased segment and performing the distal anastomosis in an end-to-end fashion.

Appropriate positioning of the graft is essential to avoid kinking or compression of the graft, which is directly responsible for most eventual failures of this operation. Several maneuvers have been described to create adequate space to accommodate the graft, including ligating the brachiocephalic vein and resecting the innominate artery. Properly gauging the length of the graft avoids leaving a redundant portion of the graft that will be prone to either kinking or traversing anterior to the aorta and being compressed by the sternum. To avoid overestimation, the sternal retractor is released before the graft length is determined. Theoretically, single-branch grafts have the advantage of being less bulky than bifurcated grafts. When bifurcated grafts are used, the common trunk should be left longer, which makes the flow more laminar at the bifurcation of the graft by reducing interference from the high flow of the ascending aorta. In certain circumstances, the lack of intrathoracic domain may preclude proper placement of a bypass graft. These circumstances include a mediastinal reoperation, saphenous vein conduits placed in certain locations during previous coronary artery bypass grafting (CABG) operations, extensive periaortic inflammation, and stents inserted during previous endovascular interventions. Endarterectomy may be preferred to bypass techniques in these circumstances.

Innominate Artery Stenting. Endovascular options for innominate artery disease have been expanding in the past decade. Initial reports had important limitations, including small numbers of patients, short follow-up

periods, and grouping of the data with data from patients with subclavian artery disease, which tends to skew the results.³¹ Only a few studies have examined stenting as a treatment for isolated innominate artery lesions.³⁹⁻⁴² The technical success rate varies from 83% to 96%; stenotic lesions have a higher treatment success rate than total occlusions do. Although early primary and secondary patency rates are excellent ($>95\%$ and $>98\%$, respectively, at up to 2 years), long-term data vary, showing primary patency rates around 70%.

The endovascular approach can be antegrade via the common femoral artery, retrograde via the brachial artery, or a hybrid approach through a retrograde cervical cut-down of the CCA. Innominate artery stenting is particularly useful in treating short-segment disease. In contrast, endovascular stenting should be avoided in long-segment occlusion of brachiocephalic vessels or extensive vessel calcifications because it can increase the risk of complications and poor treatment outcomes, including vessel rupture, catheter-induced cerebral embolization, and vessel occlusion.^{43,44}

The major advantages of endovascular treatment include a reduction in periprocedural morbidity and mortality; the risk of any neurologic deficit ranges from 2% to 4%, while the risk of minor complications hovers at approximately 6%, and the risk of major complications ranges from 1% to 2%.³⁹⁻⁴² Endovascular approaches also offer the benefits of a less invasive approach, a shorter hospital stay, and greater acceptance by patients. The lack of long-term durability data, however, maintains open operation as the first-line treatment for young, otherwise healthy patients who may derive long-term benefit from an open procedure.

Common Carotid Artery Occlusive Disease

Common carotid artery occlusive diseases are usually due to retropropagation of thrombus secondary to occlusion at the carotid bifurcation; less often, these diseases are due to primary ostial disease. There are several approaches to managing carotid bifurcation disease, and any of the techniques could be expanded to include retrograde endarterectomy via transcervical approaches. In patients with CCA occlusion, two key factors must be ascertained before a transcervical or transthoracic approach can be contemplated: (1) the presence or absence of carotid bifurcation disease and (2) whether there is concomitant involvement of the other major branches of the aortic arch.

Common Carotid Artery Bypass. For patients with isolated proximal CCA occlusion and sparing of the carotid bifurcation, a transcervical approach, such as carotid-subclavian bypass or transposition, can be used (Fig. 73-4). It is essential to ensure the patency of the carotid bifurcation and the absence of any proximal subclavian artery disease before this technique is contemplated. In cases of multivessel disease involving the arch branch vessels or common carotid arteries, a transthoracic approach with direct CCA revascularization should be considered. Transthoracic approaches are used selectively in patients with multivessel disease and extensive proximal CCA disease that spares the carotid bifurcation.

FIGURE 73-4 ■ A left subclavian-to-carotid artery bypass for treatment of common carotid artery stenosis. The procedure is performed through a supraclavicular incision (*inset*) and can be used to treat subclavian artery stenosis. (From Bozinovski J, LeMaire SA, Weldon SA, et al: Hybrid repairs of the aortic arch and proximal descending thoracic aorta. *Op Tech Thorac Cardiovasc Surg* 12:167, 2007, Figure 10. Used with permission. Copyright Elsevier.)

An aorta-to-CCA bypass with a bifurcated tube graft is preferable when both the subclavian and common carotid arteries are involved.

In all cases of CCA reconstruction, preoperative workup should establish the patency of the distal carotid vessels before any operative intervention is undertaken. Most patients who have occluded CCAs also have occluded internal carotid arteries (ICAs). Only rarely, ICA patency exists above a CCA occlusion through collateral flow via the ipsilateral external carotid artery or an aberrant branch of the ICA. Contralateral carotid occlusion, even if asymptomatic, poses a significant additional risk for perioperative stroke in such patients. Although the natural history of asymptomatic proximal CCA occlusion in patients with patent ICAs is unknown, it is likely benign, and surgery is not indicated in these circumstances.⁴⁵ Many surgeons might not consider reestablishing flow in patients with chronic asymptomatic total carotid occlusion, because the incidence of stroke is high during reestablishment of flow, and interventions might not necessarily be beneficial in preventing stroke.

Carotid Endarterectomy with Retrograde Stenting of the Innominate or Left Common Carotid Artery.

In patients with carotid bifurcation disease with retropropagation of the thrombus or concomitant proximal CCA or innominate artery disease, several authors have proposed performing a concomitant transcervical carotid endarterectomy (CEA) with retrograde endarterectomy or angioplasty and stenting.^{46,47} In this treatment approach, CEA is generally done first using local or general anesthesia. Before closing the carotid arteriotomy, the operator inserts a 7-French introducer sheath in retrograde fashion and places a vascular clamp distally to reduce the likelihood of cerebral embolization. After the stent is positioned, the sheath is withdrawn, permitting the arteriotomy incision to be closed. If open exposure of a carotid artery is performed strictly for access to a lesion that involves either the proximal innominate or carotid arteries, an 18-gauge needle and a Bentson wire are often used to cross the lesion, allowing an introducer sheath to be placed and the stent to be positioned. In addition, a stent may be placed in the

proximal innominate artery stent via a right carotid cutdown. To close the arteriotomy, a figure-of-eight suture (typically made with 5-0 polypropylene suture) is placed around the introducer sheath. Another approach involves widening the lumen with patch angioplasty; typically, this is used in cases of diseased vessels or simultaneous bifurcation disease.

A recent meta-analysis by Sfyroeras and colleagues⁴⁸ used data from the largest collection of patients to undergo hybrid treatment for high-grade tandem stenoses of the carotid bifurcation and either the proximal left CCA or the innominate artery. Thirteen studies, which included a total of 133 patients, were identified (proximal lesions were in the ipsilateral CCA in 85 cases and the innominate artery in 48 cases). In the most recent studies, a primary stenting strategy with balloon-expandable stents was most often used. The authors reported a technical success rate of 97%, with low 30-day rates of mortality (0.7%) and stroke (1.5%). Among the 13 studies, mean follow-up ranged from 12 to 36 months; during this time, 5 patients exhibited symptoms of cerebral ischemia, and 17 patients died. Of the 79 patients who received stents, 3 patients (3.7%) developed restenosis, compared with 7 (14%) of the 50 patients treated with angioplasty alone. The authors attributed the low procedural risk to the distal placement of the clamp on the ICA prior to retrograde angioplasty, which reduces the likelihood of cerebral embolization.

Subclavian Artery Occlusive Disease

The left subclavian artery is the arch vessel most commonly occluded by atherosclerosis, even in patients with multifocal disease. The subclavian artery supplies blood to the arm and to the posterior cerebral and cerebellar circulation. Proximal subclavian artery stenosis can result in symptoms originating from either territory because of competition for flow distribution. In patients who have undergone CABG surgery, the presence of a patent ITA graft to the left anterior descending coronary artery (LAD) adds another potentially competing territory. Proximal subclavian artery occlusive disease has various manifestations, including vertebrobasilar insufficiency from posterior cerebral circulatory compromise or from upper-extremity claudication or ischemia, and recurrent heart failure or angina in patients with left ITA-to-LAD grafts (see Fig. 73-1). Intervention is generally not indicated for isolated asymptomatic subclavian stenosis, because isolated proximal artery stenosis is unlikely to cause stroke if the carotid vessels are patent. However, the likelihood of stroke is greater in patients with multivessel disease; therefore, a complete evaluation of the cerebral vasculature is essential, even in patients with symptoms pertaining to the subclavian territory alone. Isolated subclavian artery symptoms, therefore, do not necessarily indicate isolated subclavian artery disease, and patients with such symptoms may require intervention.

Subclavian Artery Bypass. The aim of any treatment strategy for subclavian artery occlusive disease, be it operative bypass or endovascular stenting, is to restore

antegrade flow in both the vertebral and distal subclavian vessels—in essence, to prevent retrograde steal. From an operative perspective, this therapeutic objective can be accomplished with various surgical approaches, which include subclavian-carotid bypass grafting (see Fig. 73-4), subclavian-carotid transposition, vertebral artery transposition to the CCA, and extra-anatomic axillary bypass. In addition, for patients with isolated proximal left subclavian artery occlusive disease, a descending aorta-to-left subclavian artery bypass proximal to the origin of the left vertebral artery may be accomplished with a left thoracotomy approach. These operative strategies have been associated with excellent outcome and a low incidence of symptom recurrence.

Subclavian Artery Stenting. Advancements in endovascular intervention have resulted in remarkable treatment outcomes by providing a less invasive percutaneous approach. Catheter-based primary stenting of the subclavian arteries can be safely performed and produce satisfactory midterm outcomes.^{49,50} In one of the largest series of endovascular repairs of occlusive lesions of the subclavian artery, Sixt and colleagues⁴⁹ reported on 99 patients treated between 1996 and 2004 with mostly (90%) atherosclerotic lesions. The overall primary success rate was 97% (less for total occlusions; 87%), with no neurologic complications and only two access-related complications. The 1-year primary patency rate was 88% for all 97 patients eligible for follow-up, 79% for the patients treated with angioplasty alone, and 89% for the patients treated with stenting ($P = 0.2$).

Routine primary stenting is recommended in most cases because it achieves longer-lasting patency and greater freedom from symptoms of atheroembolism than balloon angioplasty alone. Balloon-expandable stents exert more radial force than nitinol stents do, and they are useful in ostial subclavian lesions because these lesions are usually calcified. A 1- to 2-mm overhang of the stent into the aortic lumen is desirable for ostial lesions. For postvertebral lesions, self-expanding nitinol stents are preferred to balloon-expandable stents because the nitinol stents are more pliable and less likely to be deformed by extrinsic compression.

In patients with coronary-subclavian steal syndrome (CSS), caution is exercised to prevent inadvertent occlusion of the takeoff of a patent left ITA-to-LAD graft when these stents are deployed. If technically feasible, stents should be deployed in a manner that does not compromise the origins of the ITA and vertebral artery. Dietrich and colleagues⁵¹ have shown that CSS can be treated with angioplasty and stenting; rates were 86% for primary patency and 100% for assisted-primary patency after 29 months of follow-up.

Clinical patency is accomplished in more than 80% of patients at 5-year follow up, and 80% of patients are symptom-free for more than 3 years. Complications related to endovascular interventions include stroke, atheroembolism, dissection, and complications related to the access site, such as bleeding, dissection, pseudoaneurysm, stenosis, and thrombosis. Surgery is now typically considered a second-line intervention to be used when endovascular approaches fail.^{52,53}

Multivessel Occlusive Disease

Multivessel involvement is noted in 25% of all cases of intrathoracic aortic arch branch-vessel disease, although reports of some large series note a prevalence in excess of 60%.^{7,27,34} Hence, thorough preoperative diagnostic imaging is necessary, even in patients with isolated symptoms involving a single branch territory. Transsternal aortic branch bypass appears to be the procedure best suited to these situations, and it can be carried out in one of two ways: creating multiple grafts from the aorta to individual vessels, or using branched or bifurcated grafts (see Fig. 73-2). Again, it is essential that aortic manipulation be kept to a minimum, because these patients have significant concomitant aortic arch disease; thus, the best approach may be to place a single-trunk tube graft with branches of appropriate size. The operative challenge in this circumstance is ideally positioning the bulky graft and its branches in an already compromised supra-aortic territory. It is important to position the graft along the greater curvature of the aortic arch and to tailor the length to minimize kinking or compression from surrounding structures.

Takayasu Arteritis

The treatment of Takayasu arteritis involves a combination of immunosuppressive therapy and percutaneous or surgical interventions. The first line of medical therapy remains glucocorticoids; antimetabolites are the second-line drugs in unresponsive cases.^{54,55} Surgical intervention is indicated in patients with symptomatic stenotic lesions or concomitant aneurysm formation. It is important to determine the prognostic stage—determined by using the Ishikawa criteria, which include existing complications, the pattern of the past clinical course, and the erythrocyte sedimentation rate—when considering surgical intervention.⁵⁶ Surgical treatment for patients with Takayasu arteritis might increase survival in those with stage 3 disease, but not in those with stage 1 disease.⁵⁶ Thus, conservative treatment is generally suggested for stage 1 or 2 disease, and most surgeons prudently avoid surgical intervention until the disease has reached a chronic fibro-occlusive stage.

In 1951, Shimizu and Sano⁵⁷ described surgical treatment for occlusive disease of the aortic arch branches in a patient with Takayasu arteritis. The principles of surgical bypass grafting described in the preceding sections apply to most patients, with a few notable exceptions as described here. Several techniques have been used, including endarterectomy with patch angioplasty, resection with interposition grafting, and bypass techniques. Innominate artery stenosis should be dealt with through distal grafting and not endarterectomy. Panarteritis and fibrosis yield an inconsistent plane for endarterectomy, and the adventitia that reconstitutes the vessel is often affected. Moreover, the stenotic lesions affect long segments of the supra-aortic trunk, making bypass procedures technically more feasible.⁵⁸ The disadvantage of bypass procedures, however, is the risk of subsequent pseudoaneurysm formation at the suture lines.

When proximal and distal anastomoses are constructed, sites free of disease should be chosen. Although this practice is not supported by clear scientific evidence, the absence of macroscopic disease is believed by some surgeons to decrease the likelihood of recurrent stenosis or aneurysm formation. Also, most of the involved vessels are surrounded by dense perivascular inflammation, making dissection tedious and potentially dangerous. This problem can be circumvented by planning bypass procedures such that the anastomotic sites are well away from diseased segments. Allowance should be made for progression of the disease, leading to recurrent occlusive disease; therefore, large and generous anastomoses are preferred.^{55,59,60} Subsequent aneurysm formation also needs to be considered in surgical treatment of Takayasu arteritis. Hence, the patients require lifelong follow-up with CT, MRI, or Doppler ultrasonography to monitor for the development of aneurysms. Systemic inflammation or steroid administration has little influence on anastomotic aneurysm formation. Anastomotic aneurysms tend to arise after operations for prior aneurysmal lesions and can develop any time after the initial operation. No specific factor, except the presence of an aneurysmal lesion, seems to predict recurrent aneurysm formation. The cumulative incidence of anastomotic aneurysm at 20 years is reported to be nearly 14%.⁶¹

Although no operative technique has been shown to have significant influence on the postoperative incidence of recurrent disease or aneurysm formation, surgeons prefer to operate on patients with Takayasu arteritis during the quiescent stage of the disease, using felt or bovine pericardial patches and reinforcement sutures to decrease the risk of recurrent aneurysm. Concomitant use of endovascular techniques with medical management has helped to reduce mortality to less than 10% and to improve 10-year graft patency to approximately 70%. Recently, endovascular stenting has been used to treat de novo thoracic aortic aneurysm and stenotic disease secondary to Takayasu arteritis, although the long-term consequences of using this approach remain unknown.⁶²⁻⁶⁴

CORONARY-SUBCLAVIAN STEAL SYNDROME

When a reversal of flow occurs in a previous ITA coronary bypass, myocardial ischemia can occur and result in CSS syndrome (see Fig. 73-1). The resulting ischemic pain can be confused with exertional chest pain of myocardial origin when patients report chest pain from strenuous upper-extremity activity. Often, CSS syndrome occurs in patients with an ipsilateral ITA coronary conduit and proximal subclavian artery stenosis. However, CSS has been reported in cases of inflammatory arteritis involving the proximal subclavian vessels, hemodialysis fistula in the ipsilateral upper extremity, and specific anomalies of the brachiocephalic arteries (dextro-transposition of the left subclavian artery and pulmonary artery).^{65,66}

Clinical manifestations include “silent” ischemia, ischemic cardiomyopathy, generalized heart failure, myocardial infarction (MI), and possibly sudden death. The CSS syndrome can be prevented by identifying patients who

have or may be at risk for developing subclavian artery occlusive disease.⁶⁷ Steal syndrome and myocardial ischemia can develop if substantial subclavian disease is present but untreated before placement of an ipsilateral ITA coronary conduit.⁶⁸ All patients undergoing evaluation before CABG in which the use of ITA grafts is anticipated are examined for ischemia (upper-extremity or cerebrovascular ischemia), bruits (cervical or supraclavicular), and a blood pressure differential of more than 20 mm Hg in the upper extremities. During coronary arteriography, brachiocephalic arteriography should be done in patients with suspected diffuse atherosclerotic vascular disease for better identification of subclavian artery occlusive disease.⁶⁹

In patients with significant brachiocephalic disease who are to undergo CABG surgery, options for preventing CSS include using all-vein conduits, using an ITA conduit once brachiocephalic reconstruction is completed, and using free ITA grafts or radial artery conduits during CABG. In patients who develop CSS after CABG, symptoms can be relieved by aortic-subclavian bypass, carotid-subclavian bypass, transposition of the ITA, or endovascular procedures.⁷⁰

CONCURRENT CAROTID AND CORONARY ARTERY ATHEROSCLEROSIS

Overview

The treatment of patients with multisite arterial disease, specifically those with severe carotid disease who also require CABG, is challenging and controversial.⁷¹⁻⁷³ The current guidelines suggest that carotid revascularization with CEA or carotid artery stenting (CAS) either before or concurrent with CABG surgery is a reasonable strategy in symptomatic patients with substantial carotid stenosis (>80%; class IIa recommendation, level of evidence C).⁷⁴ Furthermore, the safety and efficacy of performing carotid revascularization before or concurrently with surgical coronary revascularization are clear in patients with severe or lesser asymptomatic carotid stenosis (class IIb recommendation, level of evidence C).⁷⁴ It is important to note that these guidelines stem from expert consensus and that there is a general lack of evidence to guide clinical choice. Most experts agree that carotid revascularization is indicated if the lesion is symptomatic, bilateral, or both. However, patients in this population most often have unilateral, asymptomatic disease for which carotid revascularization before or at the time of CABG might not improve clinical outcomes when compared with optimal medical therapy and CABG.⁷⁵⁻⁷⁷

In patients referred for CABG, the prevalence of ≥50% carotid stenosis was between 10% and 22%, and the prevalence of ≥80% carotid stenosis was between 4% and 10%.⁷⁸ The 2011 American CABG guidelines indicate that duplex scanning is a reasonable option in select high-risk patients (patients ≥65 years old and those with left main disease, peripheral artery disease, diabetes, or a history of TIA or stroke, hypertension, or smoking; class IIa, level of evidence C).⁷⁹ The 2011 European peripheral artery disease guidelines recommend carotid duplex

ultrasonography in older patients (patients ≥70 years of age), as well as patients with a history of cerebrovascular disease, carotid bruit, multivessel coronary artery disease, or peripheral artery disease (class I, level of evidence B).⁸⁰

Stroke is a devastating complication of cardiac surgery and is associated with increased major disability and mortality risk and with healthcare costs. Authors from the Cleveland Clinic reported a stroke rate of 1.6% among 45,432 isolated CABG patients.⁸¹ Patients who had a stroke had significantly higher in-hospital mortality (19% vs. 3.7%), as well as poorer long-term outcomes, compared with propensity-matched patients without a neurologic insult.

Risk Factors for Stroke after Cardiac Surgery

Many patient and surgical factors have been identified as independent predictors of postoperative stroke after cardiac surgery, including clinical characteristics, the anatomic features and symptomatic nature of the carotid disease, atherosclerosis of the ascending aorta and transverse arch, and the type of cardiac surgery (Box 73-1). The multifactorial etiology of perioperative stroke partly explains why the neurologic insult can occur in a delayed fashion and on the contralateral side to the carotid lesion.

In the most comprehensive meta-analysis published to date,⁷⁷ 166 studies regarding carotid artery stenosis or occlusion were reviewed. The 30-day incidences of

BOX 73-1 Risk Factors for Stroke after Cardiac Surgery

CLINICAL FACTORS

- Increased age
- History of TIA/stroke
- Peripheral vascular disease
- Atrial fibrillation
- Diabetes
- Hypertension
- Heart failure
- Renal failure

ANATOMIC FACTORS

- Carotid lesion
 - Degree of stenosis
 - Plaque morphology
 - Progressive stenosis
 - Contralateral stenosis/occlusion
- Atherosclerosis of ascending aorta and transverse arch

SURGICAL FACTORS

- Duration of cross-clamp and cardiopulmonary bypass
- On-pump surgery
- Open heart surgery (valve or aortic surgery)
- Redo operation
- Partial clamping of ascending aorta for proximal anastomosis

TIA, Transient ischemic attack

ipsilateral stroke and of any stroke were only 2.0% and 2.9%, respectively, among patients with unilateral, asymptomatic, 50% to 99% carotid stenosis who underwent isolated cardiac surgery without prophylactic carotid revascularization. In asymptomatic patients, these risks did not increase with stenosis severity. In contrast, patients with a history of stroke, TIA, or severe bilateral carotid disease had markedly increased rates of postoperative death and stroke. Additional subanalysis of 26 published reports with a total of 2531 patients showed that when symptomatic patients were also included, patients with 50% to 99% stenosis or occlusion had a 7.4% stroke risk after cardiac surgery; this risk increased to 9.1% in patients with 80% to 99% stenosis or occlusion. The risk of stroke was 6.5% in patients undergoing cardiac surgery with bilateral, asymptomatic, 50% to 99% stenosis, or 50 to 99% stenosis with contralateral occlusion. The risk of death or stroke in such patients was 9.1%. The importance of neurologic symptoms was also shown in an earlier meta-analysis of patients with carotid stenosis who underwent CABG: patients with previous TIA or stroke had a postoperative stroke rate of 8.5%, compared with 2.2% in asymptomatic patients (odds ratio, 3.6).⁸² A few centers have reported no increased stroke by limiting carotid revascularization in CABG patients with asymptomatic carotid stenosis.^{83,84} In a large retrospective study of 4335 patients, the risk of perioperative stroke was significantly increased in the synchronous CEA-CABG group compared with the group that underwent CABG alone (15.1% vs. 0%; $P = 0.004$).⁸⁵

It is generally understood that stroke after cardiac surgery among patients with asymptomatic carotid disease is relatively rare. Furthermore, since the early pivotal randomized trials comparing medical therapy to CEA were performed, contemporary optimal medical therapy has improved considerably. Thus, many argue that if such trials were performed with today's optimal medical therapy (e.g., modern antiplatelet, lipid-lowering, antihypertensive regimens), the previously reported benefit of CEA over medical therapy in asymptomatic patients (5% to 6% vs. 11% to 12%, respectively, for a combined death or stroke rate at 5 years) may be less compelling.⁸⁶⁻⁸⁸ These data call into question the rationale for performing prophylactic carotid revascularization in neurologically asymptomatic patients with unilateral carotid disease. Importantly, among 27,084 patients in the United States who underwent synchronous carotid and coronary revascularization procedures between 2000 and 2004, the vast majority (>95%) had asymptomatic carotid disease.⁸⁹

Surgical Approaches to Concurrent Carotid and Coronary Disease

Strategies to address concomitant, surgically correctable carotid and coronary disease include synchronous CEA and CABG, staged repair with either CEA or CAS followed by CABG, "reverse" staged repair (CABG then CEA or CAS), or no treatment of the carotid disease (CABG alone). The aim of any operative strategy is to minimize the risk of specific major adverse cardiovascular events. The staged and reverse-staged approaches risk

between-stage events such as death, stroke, or MI; this is not entirely unexpected, given that patients might have a severe form of coronary artery disease. Although conducting a carotid intervention before CABG has the advantage of lowering the patient's risk of peri-CABG stroke, the risk of acute MI is still high in the timeframe surrounding the carotid intervention and during the interval between the two interventions. Performing CABG before carotid intervention, on the other hand, could be associated with a high stroke rate. The approach must be individualized to the patient at hand, with careful attention to the symptomatic territory and institutional experience with various strategies. Because no randomized trial has yet compared management strategies for carotid disease at the time of cardiac surgery, the interpretation of available data from observational studies has inherent limitations.

Synchronous Carotid Endarterectomy and Coronary Artery Bypass Grafting

Since the introduction of the concept by Bernhard and colleagues⁹⁰ in 1972, the combined surgical approach has remained a topic of controversy. In the decade from 1992 to 2002, combined CEA-CABG represented only a small portion (1.1%) of all CABG procedures in the United States.⁹¹ In an excellent review of the literature that summarized outcome data from patients ($n = 11,854$) with carotid and coronary disease who underwent synchronous CEA-CABG, Venkatachalam and colleagues⁷² reported an early mortality rate of 5%, a stroke rate of 4%, an MI rate of 3%, and a death, stroke, or MI rate of 10%. Similarly, Timaran and colleagues⁸⁹ reported a mortality rate of 5.2%, a stroke rate of 3.9%, and a death or stroke rate of 8.6% among 26,197 patients who underwent combined CEA-CABG.

Using the Nationwide Inpatient Sample (NIS) database, Gopaldas and colleagues⁹² compared patients who underwent staged repair (CEA before or after CABG during the same admission but not on the same day; $n = 6152$) with patients who underwent synchronous repair (both procedures on the same day; $n = 16,639$). Patients who underwent synchronous CEA-CABG had an in-hospital mortality rate of 4.5%, a stroke rate of 3.9%, and a death or stroke rate of 7.7%. The staged patients had similar mortality (4.2%) but higher morbidity, including more cardiac, wound, respiratory, and renal complications. Among patients who undergo combined procedures, the stroke rate tends to be highest (>10%) in patients who have contralateral carotid occlusion. The presence of neurologic symptoms significantly increases the risk of postoperative death or stroke after combined carotid interventions and coronary bypass (odds ratio, 4.9; $P < 0.001$).⁸⁹

Staged Approach: Carotid Revascularization Followed by Coronary Artery Bypass Grafting

The staged approach involves operative intervention on the diseased carotid vessels followed by myocardial

revascularization, with the obvious theoretical benefit being the reduction of stroke risk during CABG. The risk of MI in the peri-CEA period and during the time interval between the two procedures remains the major drawback of this approach. Takach and colleagues⁹³ reported a low overall stroke rate of 1.9% with the staged approach. In their series, 512 patients underwent intervention for comorbid carotid and coronary disease over a period of 21 years. Before 1986, the incidence of adverse events was greater in patients who underwent combined procedures than in those who had staged interventions (9.4% vs. 2.6%; $P < 0.01$). However, since 1986, both groups have had similar rates of stroke (1.9% vs. 2.0%), death (3.8% vs. 3.0%), and MI (3.8% vs. 5.0%). In this series, approximately 30% of strokes occurred in the contralateral cerebrovascular territory in both the staged and the simultaneous groups. Hemodynamic instability or arrhythmia accompanied 10 of the 15 strokes that occurred during both the synchronous and the staged procedures. Advances in anesthesia, surgical technique, intraoperative monitoring for cerebral ischemia, and myocardial protection have all improved surgical teams' ability to maintain perioperative hemodynamic stability in patients with combined disease. The improvement in neurologic outcomes that occurred after 1986 in patients who underwent combined procedures in this series was attributed to these advances. The risk of stroke was affected by neither the use of a carotid shunt nor the use of patch closure of the carotid arteriotomy. Operative approach (synchronous or staged) was not a predictor of either stroke or death. The staged approach, however, lengthened hospital stay, increased the cost of hospitalization, and raised the risk of acute ischemia and MI in the interval between the CEA and CABG procedures.

Clearly, preventing stroke in patients with coronary disease is a multifactorial problem. Although carotid bifurcation disease may be a major contributing factor for perioperative stroke, it does not directly explain strokes in the contralateral territory, which occur in approximately one third of patients. More than anything else, the presence of carotid bifurcation disease is a marker for generalized atherosclerosis, which by itself increases the risk of hemorrhage, hemodynamic instability, cardiac failure, and atheroemboli. Also, the fact that adverse outcomes are more frequent in patients who undergo combined or staged procedures than in patients who undergo isolated CABG or CEA suggests that patients with concomitant carotid and coronary disease are at greater risk overall and have a poorer physiologic performance status, possibly secondary to diffuse atherosclerosis.

Reverse Staged Approach: Coronary Artery Bypass Grafting Followed by Carotid Endarterectomy

The advantage of the reverse staged approach is that the risk of MI is minimized by intervention on the coronary vessels before a CEA is performed. Unlike the staged approach, in which the elimination of hemodynamically significant carotid stenosis removes only one of the many potential causes of stroke during CABG, a reverse staged

approach essentially eliminates the one major and clearly defined complication of CEA: MI. The meta-analysis by Naylor and colleagues⁹⁴ found that perioperative MI rates were lowest after the reverse staged procedure (0.9%; 95% confidence interval [CI], 0.5-1.4) and were highest in patients who underwent staged CEA-CABG (6.5%; 95% CI, 3.2-9.7). However, patients with reverse staged procedures (CABG-CEA) had a higher risk of ipsilateral stroke (5.8%; 95% CI, 0.0-14.3) and of any stroke (6.3%; 95% CI, 1.0-11.7) than patients with other operative approaches (synchronous or staged).

In a recent randomized trial, 185 patients with asymptomatic unilateral carotid stenosis greater than 70% underwent CEA either early (before or concomitantly with CABG; $n = 94$) or late (1 to 3 months after CABG; $n = 91$).⁹⁵ All patients had general anesthesia, and CEA routinely involved carotid artery shunting. Although early death rates were similar between groups (1.0% vs. 1.1%; $P = 0.98$), there was a significant difference between groups concerning combined 90-day stroke and death rate; this was substantially lower in the early CEA group (1.0% vs. 8.8%; $P = 0.02$). Furthermore, delayed CEA significantly predicted combined stroke and death at 90 days (odds ratio, 14.2; $P = 0.03$). Thus, it was found that CEA before or concomitantly with CABG surgery greatly lowers the risk of stroke.

Carotid Artery Stenting Followed by Coronary Artery Bypass Grafting

Endovascular approaches have pushed the envelope further amidst the controversy surrounding the treatment of patients with combined coronary and carotid disease.⁹⁶ A retrospective study by Timaran and colleagues⁸⁹ of NIS data has provided interesting insights into CAS before CABG. During the 5-year period from 2000 through 2004, 27,084 patients underwent carotid revascularization and CABG during the same hospitalization. Of these patients, 96.7% underwent either staged or synchronous CEA-CABG, and only 3.3% underwent CAS-CABG. Patients who underwent CAS-CABG tended to have fewer major adverse events than did those who underwent CEA-CABG. Specifically, CAS-CABG patients had significantly lower incidences of in-hospital stroke (2.4% vs. 3.9%; $P < 0.001$) and combined stroke and death (6.9% vs. 8.6%; $P < 0.001$) than did CEA-CABG patients; however, the incidence of in-hospital death was similar (5.2% vs. 5.4%) between the two groups. The study, however, did not include separate comparisons either between CAS-CABG and staged CEA-CABG or between CAS-CABG and synchronous CEA-CABG. Unfortunately, typically reported 30-day data were not available in the NIS dataset, and only in-hospital events were captured; thus, major adverse events could be greater than presented. Ziada and colleagues⁹⁷ compared 30-day outcomes between staged CAS-CABG ($n = 56$) and combined CEA-CABG ($n = 112$) groups. Although no significant difference was found for combined death, MI, or stroke ($P = 0.12$), after propensity adjustment, a nearly significant difference was noted for lower stroke or MI rates in the CAS-CABG group.

A prospective, single-center study from Europe examined outcomes in 356 patients who underwent staged CAS followed by CABG.⁹⁸ None of the patients had symptoms of carotid disease in the 4 months preceding CAS, and patients with major neurologic deficits, diffuse common carotid disease, chronic total occlusions, and preocclusive or string sign lesions were excluded. Cardiac surgery occurred with a mean delay of 22 days (range, 14 to 30 days). Despite aspirin and clopidogrel being withheld for 5 days before surgery, there were no cases of carotid stent thrombosis. Following CABG, the 30-day cumulative incidence of death, MI, or stroke was 8.7%. At nearly 3 years' follow-up, the authors reported a remarkable neurologic death rate of 1.1% and a major ipsilateral stroke rate of 1.1%.

As reported by Mas and colleagues,⁹⁹ in patients with isolated yet symptomatic carotid disease (>60% stenosis), CAS produced outcomes inferior to those of the gold standard treatment, CEA. The trial was stopped prematurely when preliminary analyses showed that the incidence of stroke or death was 3.9% after CEA (95% CI, 2.0-7.2) and 9.6% after CAS (95% CI, 6.4-14.0) and that the 30-day incidence of disabling stroke or death was 1.5% after CEA versus 3.4% after CAS. Likewise, the incidence of perioperative stroke was reported to be fivefold higher in symptomatic patients undergoing CAS-CABG than in symptomatic patients undergoing CEA-CABG. However, Versaci and colleagues¹⁰⁰ have supported the feasibility of sequential hybrid CAS immediately followed by CABG; in their 37 patients, the combined incidence of disabling stroke, MI, or death was 8.1%.

The most comprehensive study comparing the three most common surgical strategies for concomitant carotid and coronary artery disease comes from a retrospective review of 350 patients treated at the Cleveland Clinic from 1997 to 2009.¹⁰¹ The majority of patients had asymptomatic disease (81%) and underwent CABG with or without concomitant valve surgery (92%); only 8% of these patients had open heart surgery (OHS) that did not involve CABG (e.g., isolated valve or aortic repair). The study compared three groups: combined carotid endarterectomy and OHS under a single anesthetic (combined CEA-OHS; $n = 195$), staged carotid endarterectomy followed by open heart surgery (staged CEA-OHS; $n = 45$), and staged carotid stenting followed by open heart surgery (CAS-OHS; $n = 110$). In staged CEA-OHS, CEA was performed a median of 14 days before OHS, whereas in the staged CAS-OHS group, patients underwent 3 to 4 weeks of antiplatelet therapy (median interval, 47 days) between CAS and CABG. The authors performed a propensity-adjusted analysis examining the early (up to 1 year) and late (beyond 1 year) risks of the composite endpoint (all-cause death, stroke, and MI). In the early phase, the staged CAS-OHS group's risk of adverse events was similar to that of the combined CEA-OHS group, whereas the staged CEA-OHS group had more adverse events, primarily driven by a higher inter-stage MI rate. Early mortality rates were similar among all three treatment strategies. Beyond 1 year, the staged CAS-OHS group experienced fewer adverse events than either the staged CEA-OHS group (adjusted hazard ratio 0.33; $P = 0.01$) or the combined CEA-OHS group

(adjusted hazard ratio 0.35; $P = 0.003$) did. This late divergence was largely due to increased all-cause mortality in the staged and combined CEA groups. The systematic analysis of all interstage events and the direct comparison of three treatment strategies with a median follow-up of 3.7 years were the strengths of this study. The findings suggest that for patients who require urgent CABG, combined CEA-CABG is the optimal strategy for revascularization. However, for patients with stable angina who could tolerate a few weeks of dual-antiplatelet therapy, staged CAS-CABG may be advantageous. Staged CEA followed by CABG is associated with increased short-term MI and long-term mortality and may not be the optimal approach.

Synchronous Off-Pump Coronary Artery Bypass Grafting and Carotid Endarterectomy

Off-pump CABG has the potential advantage of reducing aortic manipulation, which is a major risk factor for embolic stroke. However, in the largest reported series ($n = 358$), Mishra and colleagues⁶¹ found no significant difference in major adverse cardiovascular events between conventional CABG and off-pump CABG when CEA was performed simultaneously. The difference between off-pump and conventional CABG in terms of stroke rate and outcomes is a separate issue and is beyond the scope of this chapter. Suffice it to say, there is no evidence that this approach to treating concomitant coronary and carotid disease is superior to others that use cardiopulmonary bypass during CABG.

SUMMARY

The surgeon's approach to concurrent severe carotid and coronary artery disease must be individualized to the patient's anatomy, clinical presentation, and comorbid diseases. The clinical challenge is to balance sufficient repair of multisite arterial disease with minimal adverse outcomes, specifically perioperative MI, stroke, and death, including interstage events for staged procedures. In the absence of large-scale randomized trial data, carefully designed retrospective studies provide the best evidence available to guide clinical decision making. The differences in reported outcomes stem from clinical heterogeneity and differences in study design, comparator groups, surgical era, and analytical methods. Experts agree that when significant symptomatic or bilateral carotid artery stenosis is present, whenever possible, carotid revascularization is generally indicated in patients with planned CABG surgery.⁷³ Both the mode (CEA vs. CAS) and the timing (before, during, or after CABG) of carotid revascularization depend largely on the patient's symptoms, as well as on institutional experience. Synchronous, staged, and reverse-staged procedures have each been performed with a low incidence of morbidity and mortality. For patients with unilateral asymptomatic carotid artery stenosis, there might not be a benefit to routine carotid intervention as compared with

contemporary optimal medical therapy and CABG alone. Further studies are needed to elucidate the roles and timing of CEA, CAS, and optimal medical therapy in the management of patients with concomitant severe carotid and coronary artery disease.

Acknowledgments

The authors wish to thank Scott A. Weldon, MA, CMI, for assisting with the illustrations; Stephen N. Palmer, PhD, ELS, and Susan Y. Green, MPH, for editorial assistance; and Raja R. Gopaldas, MD, and Peter H. Lin, MD, for their substantial contributions to the chapter published in the previous edition of this textbook, on which this updated chapter was based.

Peripheral arterial occlusive disease (PAD) is a major cause of disability, loss of work, and lifestyle changes. The natural history of PAD is often characterized by slow progression in symptoms over time.¹⁻⁵ However, 70% of patients will remain stable or improve over time, approximately 30% will require an intervention, and 10% will require amputation.⁶ Limb loss is the tragic final outcome of PAD and is associated with a significant degree of disability and a poor overall prognosis.⁷ The aging of the population, continued tobacco abuse, high-fat diets, sedentary lifestyles, and rising prevalence of obesity parallel the increasing prevalence of PAD. The prevalence of PAD in the general population is 3% to 10%, and it is 15% to 20% among patients older than 70 years.⁸ This prevalence probably underestimates the true burden of disease, however, as PAD may be asymptomatic. Because of the rising prevalence of PAD, many cardiovascular specialists have adopted a strategy of “global vascular management” for their patients. In this strategy, the evaluation, care, and intervention plan is more comprehensive in its scope, and it includes the management of vascular disease in all of its manifestations and anatomic locations. This chapter reviews the general aspects of peripheral vascular disease, with particular emphasis on the angiographic and percutaneous interventions after medical evaluation.

PERIPHERAL ANGIOGRAPHY

Indications

The purpose of peripheral angiography is to define the vascular anatomy and to identify significant arterial narrowing that requires revascularization (either percutaneous or surgical). As with any invasive diagnostic test, the risk-benefit ratio should be evaluated before angiography to identify patients who might fully benefit from imaging.⁹⁻¹¹

Lower extremity claudication is classified according to the level of debilitation or restriction of activities. It is important to select the appropriate patient for angiography, given that the morbidity from vascular access might be particularly high among patients with PAD. The most commonly used clinical grading system for PAD is the Rutherford-Becker scale, a 7-point scale from 0, which denotes asymptomatic disease, to 6, which denotes major tissue loss (Table 74-1). In general, patients with Rutherford scale 2 and higher and noninvasive studies that demonstrate evidence of significant disease are likely to benefit from angiography and revascularization. Any patient with symptomatically limiting lower extremity claudication should undergo angiography to fully define the anatomy with a consideration toward revascularization.

TABLE 74-1 Rutherford Scale

Grade	Category	Clinical Description	Objective Criteria
0	0	Asymptomatic	Normal treadmill test
	1	Mild claudication	Ankle pressure after exercise <50 mm Hg but >25 mm Hg less than brachial
I	2	Moderate claudication	More moderate symptoms
	3	Severe claudication	Does not complete treadmill test
II	4	Ischemic rest pain	Ankle pressure after exercise <50 mm Hg
			Resting ankle pressure <60 mm Hg
			Decreased pulse volume recording
III	5	Minor tissue loss	Resting ankle pressure <40 mm Hg
		Nonhealing ulcers	Pulse volume recording moderately decreased
		Major tissue loss	As noted in category 5
	6	Loss above the metatarsal limb no longer salvageable	

Angiography is indicated in patients with threat of limb loss owing to acute thromboembolism. Patients with acute onset of a cool, pulseless extremity after catheterization or trauma require angiography to define the anatomy and site of occlusion in addition to allowing the direct infusion of intra-arterial fibrinolytic therapy or mechanical or rheolytic thrombectomy if necessary.¹²⁻¹⁷

Angiography may be warranted among patients with an abdominal aortic aneurysm or thoracic aneurysm to fully delineate the anatomy, particularly if endovascular repair is considered. However, given current noninvasive imaging techniques, such as magnetic resonance angiography and computed tomographic angiography, it is unlikely that invasive angiography is necessary to define anatomy among patients who are at low surgical risk, in whom an open repair may be most beneficial. Only if invasive angiography answers a particular question (e.g., the angle of the aneurysm neck) that cannot adequately be answered with noninvasive imaging should peripheral catheterization be pursued.

Magnetic resonance angiography may also be useful in the evaluation of coarctation of the aorta. When angiography is needed, anteroposterior (AP) and lateral images are the most useful for patients with coarctation who have not been operated on. Angiography usually confirms the anatomic coarctation, invariably seen just distal to the origin of the left subclavian artery. Further, if the head and neck vessels are imaged with the thoracic aorta, an idea of collateral flows can be inferred as well (i.e., carotid or mammary).

Invasive renal angiography is indicated in patients who have evidence of significant stenosis on noninvasive testing, such as magnetic resonance angiography and Doppler ultrasonography. Other indications include new uncontrolled hypertension in patients younger than 30 years or older than 55 years, refractory hypertension, rising creatinine concentration (specifically after the institution of angiotensin-converting enzyme inhibitor therapy), or unexplained acute pulmonary edema.¹⁸ The prevalence of renovascular hypertension may be as high as 5% in the general population and 30% among patients with coronary artery disease or other PAD.

Because of the multiple-source blood supply to the upper extremity, which is derived principally from the subclavian and vertebral arteries, upper extremity

claudication is rare. Upper extremity claudication symptoms include an inability to perform activities with the affected limb, such as combing hair, brushing teeth, or repeated lifting. Another constellation of symptoms indicating obstructive disease in the upper extremity may come from significant obstruction in the posterior circulation. In this situation, there is a reversal of flow from the vertebral artery in a patient with disease in the ipsilateral vertebral artery, leading to dizziness or difficulties with gait.¹⁹⁻²² Among patients who have undergone coronary artery bypass graft surgery with use of the internal mammary artery, persistent angina and anterior ischemia on noninvasive testing may suggest left subclavian stenosis as the cause of coronary ischemia.^{21,23-27} Therefore, any patient with symptoms of upper extremity claudication, anterior ischemia after coronary artery bypass grafting with the use of the left internal mammary artery, or posterior circulation events and a difference in upper extremity blood pressures should be evaluated for the possibility of subclavian stenosis and undergo evaluation, including angiography.

A critical stenosis of one or both carotid arteries on noninvasive imaging or evidence of transient ischemic attack or stroke and a critical stenosis identified on noninvasive testing is an indication for invasive carotid or cerebral angiography.

Contraindications

The principal contraindications to peripheral angiography are bleeding diathesis, renal failure (true or impending), fever, ongoing infection, and severe anemia (Box 74-1).

Complications

Complications of invasive peripheral angiography primarily involve vascular access site complications, catheter manipulation within atherosclerotic vessels, emboli, clot formation, stroke, myocardial infarction, worsening renal function, or congestive heart failure (Box 74-2). A particularly devastating complication of catheter manipulation within the arterial tree is an atheroembolic event. In its most severe form to the lower extremities, it may cause loss of limb or digits. Likewise, emboli to the renal

BOX 74-1 Relative Contraindications to Catheterization and Angiography

- Bleeding diathesis or inability to take aspirin or adenosine diphosphate inhibitor
- Concurrent febrile illness
- Severe renal insufficiency or anuria without dialysis planned
- Severe allergy to contrast agents
- Severe hypokalemia or digitalis toxicity
- Severe hypertension or ongoing unstable coronary syndrome

BOX 74-2 Possible Complications of Peripheral Catheterization

- Vascular access dissection or perforation: 0.1%-0.2%
- Bleeding or hematoma: 1.5%-2.0%
- Allergic reaction: 0.5%-2.0%
- Vasovagal events: 1.0%-2.0%
- Death: 0.1%-0.2%

circulation can lead to acute renal decompensation or failure requiring dialysis.²⁸⁻³⁰ Pseudoaneurysm or vascular access complications can be as high as 3% in patients with severe peripheral occlusive disease.^{31,32}

General Considerations

There are several important differences in imaging of peripheral vascular structures and coronary arteries. Peripheral angiography commonly uses a larger image intensifier field (14 inches [36 cm]) to encompass larger regions of interest. Digital (not film-based) angiography allows online display of acquired images as well as advanced processing techniques to enhance brightness, contrast, or shift of underlying bone structures to enhance the final image (Fig. 74-1). Frequently, digital subtraction angiography is used. With this imaging method, a baseline background image, referred to as a mask, is obtained immediately before injection of contrast material to digitally subtract bone, calcifications, air, or soft tissues from the final image, leading to the best image quality with the most definition of vascular anatomy. Another advantage of digital subtraction angiography is that it can reduce the volume of contrast material and imaging acquisition time required.

SPECIFIC ANATOMIC IMAGING

Thoracic Aorta

Thoracic aortography is used to define the anatomic relation of the aortic arch and the great vessels, to determine the diameter of the thoracic aorta, to obtain evidence of dissection (Fig. 74-2), and to evaluate for trauma or other vascular injuries. The optimal view of the aortic arch is obtained in the left anterior oblique projection at 30 to 40 degrees oblique. The injection of 30 to 40 mL of

FIGURE 74-1 ■ Digital subtraction angiogram of the popliteal artery with moderate motion of the patient confounding the popliteal evaluation and after “shifting” of the image to re-mask the underlying bone structures for direct angiographic evaluation of the anatomy.

FIGURE 74-2 ■ (A) Angiogram and (B) intravascular ultrasound image of a patient with type A dissection of the aortic arch. The false lumen (FL) and true lumen (TL) are evident in the intravascular ultrasound image. The arrows on the angiogram correlate with the site of the intravascular ultrasound image. DF, Dissection flap.

contrast material at 20 to 30 mL/sec generally opacifies the vessels for adequate imaging. If digital subtraction angiography is used, the patient should be instructed to hold his or her breath to avoid artifacts caused by motion or breathing. The three principal vessels originating from the arch are (1) the brachiocephalic (innominate), leading ultimately to the right subclavian and right carotid arteries; (2) the left common carotid; and (3) the left subclavian artery (Fig. 74-3). The most common normal variant of this anatomy is the so-called bovine arch, in which the left common carotid artery originates from the brachiocephalic trunk. This normal variant occurs in approximately 10% of patients.³²

Abdominal Aorta

The abdominal aorta should be angiographically imaged for evaluation of abdominal aortic aneurysm, dissection, lower extremity claudication, mesenteric ischemia, and renovascular disease. The abdominal aorta begins at the level of the diaphragm. The principal vessels are, in descending order, (1) the celiac artery at the level of L1,

FIGURE 74-3 ■ Digital subtraction angiography of the thoracic arch and great vessels. *BCA*, Brachiocephalic artery; *LCCA*, left common carotid artery; *LSC*, left subclavian artery; *RCCA*, right common carotid artery; *RSC*, right subclavian artery.

FIGURE 74-4 ■ **A**, Anteroposterior view of digital subtraction angiography of the abdominal aorta and major branches. **B**, Lateral digital subtraction angiography of the abdominal aorta and major branches. *CA*, Celiac artery; *IMA*, inferior mesenteric artery; *RA*, renal artery; *SMA*, superior mesenteric artery.

(2) the superior mesenteric artery at the level of L2-3, (3) the renal arteries at the level of L2-3 just caudal to the superior mesenteric artery, and (4) the inferior mesenteric artery at the level of L4. The abdominal aorta terminates at the bifurcation and the origin of the iliac arteries.

In general, 20 to 40 mL of contrast material injected at 15 to 30 mL/sec will adequately opacify the vessels to define the anatomy. Again, as in the thoracic aorta, it is critical to fully opacify the lumen and the vessels of interest. AP and lateral images (Fig. 74-4) of the abdominal aorta are usually sufficient to delineate all anatomic areas of interest in the abdominal aorta and mesenteric vessels. If selected conduits require further visualization, a soft-tipped catheter can provide selective angiography without requiring large loads of contrast material to fully define the anatomy.

Head and Neck Angiography

The three primary branches emanating from the aortic arch are the brachiocephalic, left common carotid, and

FIGURE 74-5 ■ Digital subtraction angiography of the left subclavian artery before and after intervention. **A**, The left subclavian artery is occluded. **B**, After crossing the left subclavian artery in a retrograde fashion from the left brachial artery, the subclavian is stented, with the final angiographic result noted.

left subclavian arteries. The right subclavian and carotid arteries are the terminal branches of the brachiocephalic trunk. The most common variant of this anatomy is the bovine arch, in which the left carotid and brachiocephalic share a common origin.³²

Subclavian artery disease, stenosis, and occlusion are common.³³ Symptoms are rare because of the dual supply of blood to the upper extremity through the subclavian and vertebral arteries. Upper extremity claudication is rare but is manifested by upper extremity discomfort while engaging in activity with the upper extremity or in activities of daily living. More commonly, subclavian stenosis or occlusion is manifested by either posterior circulation symptoms, such as dizziness and gait instability, which are rare, or anterior ischemia (coronary steal syndrome) in the patient who has been treated with left internal mammary artery coronary bypass grafting (Fig. 74-5).^{23-27,34}

Subclavian artery angiography is optimally performed with both AP and ipsilateral oblique views. Selective angiography can be performed with any straight or slightly angulated catheters. As in the thoracic aorta, nonselective angiography, in general, requires 30 to 40 mL of contrast material injected at 20 to 30 mL/sec to adequately opacify all vessels in the arch. The vessels are usually accessed with the use of the guide wire as a rail, and then the catheter is advanced over the wire. Access to the brachiocephalic, carotid, and subclavian arteries usually requires a counterclockwise movement of the catheter in the ascending aorta for it to engage the vessel of interest. The J-wire is then advanced into the vessel, and ultimately the catheter is advanced over the wire. Once the wire has been removed and the catheter has been flushed, angiography can be performed safely. There is usually some shoulder and neck discomfort with moderate injections of contrast material, and the patient should be forewarned of a sensation of warmth that will follow injections. Discomfort can be minimized, if necessary, with the use of half-diluted contrast material. Excessively vigorous injections should be avoided to

prevent subintimal injection or dye staining into the intima of the subclavian artery.

Atherosclerosis of the subclavian artery is generally proximal at the origin or within the first few millimeters from the aortic origin. The origin of the inferior mesenteric artery is usually spared of atherosclerosis. The origin of the vertebral artery may be involved with atherosclerotic disease, but the need for intervention is low because of the dual blood supply to the posterior circulation that arises from both the contralateral vertebral and ipsilateral carotid arteries with an intact intracerebral circulation.

The carotid arteries generally bifurcate at the level of the fourth cervical vertebra into the internal and external carotid arteries (Fig. 74-6A). The internal carotid usually has no major branches and becomes tortuous below the petrous bone, the so-called carotid siphon. Once the vessel enters the petrous bone, it is considered the intracranial internal carotid artery. On exiting the petrous bone, the internal carotid artery bifurcates early into the anterior and middle cerebral arteries. The external carotid artery has several branches that supply the face.

Carotid atherosclerosis is common.^{35,36} Intervention in the internal carotid artery is performed either percutaneously or surgically. Annually, there are 600,000 strokes in the United States, of which 500,000 are first attacks and 160,000 are fatal. Cerebral occlusive disease encompasses stroke, transient ischemic attack, and posterior circulation (vertebral-basilar) events. Several studies have evaluated the efficacy of various revascularization strategies in preventing future events.³⁷⁻³⁹ The National Heart, Lung, and Blood Institute's Atherosclerosis Risk in Communities study⁴⁰ reported that 83% of all strokes were ischemic, 40% were lacunar, and 14% were thromboembolic. Most patients with extracranial carotid artery disease are asymptomatic.

Risk factors for the presence and progression of carotid artery disease are similar to those of coronary artery disease and include diabetes mellitus, hypertension, hyperlipidemia, and family history. A bruit can aid in identifying patients with carotid stenoses, but the presence of a bruit is neither sensitive nor specific for the detection of clinically meaningful carotid stenosis. For

example, in one study,⁴¹ only 37% of 330 patients referred to a neurology clinic with a cervical bruit had a high-grade carotid artery lesion noted with duplex imaging. A carotid bruit may be associated with subsequent risk of stroke, as the Framingham Heart Study demonstrated that asymptomatic patients with a carotid bruit have twice the risk of stroke.⁴² In addition, a bruit can be a marker of more general cardiovascular risk.⁴³ In asymptomatic patients, risk of stroke was 2.5% if the stenosis was more than 75%. The risk was higher for patients with symptoms (3.3%).⁴⁴⁻⁴⁶

Angiography of the carotid artery is generally performed in the AP and lateral views. Selective angiography should be performed with care to ensure adequate position of the catheter and distance from the bifurcation.

Renal Vascular Imaging

The prevalence of renovascular disease can be as high as 50% in patients with coronary artery disease or other PAD.^{47,48} Renovascular disease is a cause of secondary hypertension in 0.5% to 5% of the general population.^{49,50} Whereas other noninvasive and functional studies such as Doppler ultrasonography, captopril nuclear studies, and magnetic resonance angiography remain useful screening tools, contrast angiography remains the gold standard. The renal arteries have a posterior takeoff from the abdominal aorta. Injection of 15 to 20 mL of contrast material at 30 mL/sec should opacify the intended vessels adequately. An improvement in blood pressure control is one goal of percutaneous revascularization of renal arteries.⁵¹⁻⁵³ Another potential benefit of renal artery revascularization is preservation of renal function.^{48,54-56}

Lower Extremity Angiography

Iliac Vessels

The iliac vessels originate at the termination of the abdominal aorta, usually at the L4-5 level. They remain retroperitoneal throughout their course until they cross the inguinal ligament and become the common femoral artery. The principal bifurcation in the iliac artery is the terminal bifurcation of the common iliac into the internal and external iliac arteries (Fig. 74-7).

Angiography of the iliac arteries is best achieved in the AP and oblique positions (left anterior oblique for the right internal iliac and right anterior oblique for the left internal iliac). The imaging catheter is positioned just above the aortic bifurcation to allow the best opacification of the iliac arteries. In general, 15 to 30 mL of contrast material injected at 20 to 30 mL/sec is sufficient to provide adequate opacification.

In patients with lower extremity claudication, noninvasive testing with ankle-brachial indices by duplex and Doppler imaging is critical. Evaluation with and without exercise, either 5 minutes at 1.5 miles per hour or 40 calf raises is often necessary to provoke symptoms and, more important, to determine the level of stenosis.⁵⁷ Doppler imaging is vital in the evaluation of the lower extremities. Normal flow patterns are triphasic or biphasic (Fig. 74-8). When a critical lesion is present, the waveform becomes

FIGURE 74-6 ■ **A**, Angiogram of a normal carotid and its bifurcation. **B**, Abnormality on an angiogram with an ulcerated left internal carotid artery in a patient several weeks after a transient ischemic attack. **C**, Final angiogram after angioplasty and stenting.

FIGURE 74-7 ■ Digital subtraction angiography in the anteroposterior projection of the terminal abdominal aortic bifurcation. CIA, Common iliac artery; EIA, external iliac artery; IIA, internal iliac artery.

monophasic. Furthermore, during exertion, resting triphasic and biphasic waveforms become monophasic distal to a critical stenosis. The location of the transition in the waveform pattern indicates the level of critical disease and can allow more directed and focused lower extremity angiography. Because the lower extremity arterial tree is relatively superficial, the anatomy can occasionally be directly visualized noninvasively with duplex imaging. Therefore, in some cases, the level and extent of disease may be delineated without vascular access.

Angiographic Technique

Lower extremity angiography can be performed in many ways. There has been an increase in the use of digital angiography and bolus-chase techniques, in which the table stops at various points of the run to mask the image, then returns to the same location and follows the original bolus of contrast material throughout the course. These methods allow a single injection of contrast material and delineation of the anatomy without the need for multiple

FIGURE 74-8 ■ Doppler waveforms in a normal and an abnormal lower extremity. Note the triphasic waveform in the normal patient and an attenuated, wide-based waveform consistent with a monophasic (abnormal) wave consistent with upstream stenosis or occlusion. L, Left; R, right.

injections. The principal problem with this technique occurs when there is significant motion of the patient from the mask to the contrast bolus-chase and the images are out of register and of poor quality. Small motion from the patient may be digitally shifted in the final angiogram without much difficulty to remove the underlying bone structures and to enhance the final angiographic image (see Fig. 74-1). In general, volumes of contrast material for the lower extremity bolus-chase technique range from 30 to 40 mL at 8 to 10 mL/sec. Other techniques include static images and older cut-film changers. In the static image technique, a focal area is evaluated with a single bolus injection of contrast material of 15 to 30 mL at 8 to 10 mL/sec or by hand injection.

One unique aspect of peripheral angiography is the antegrade puncture of the femoral artery. The common femoral artery is entered as with standard retrograde access, but it is entered in the antegrade direction (in the direction of blood flow to the leg). The entry is less steep (≈ 45 degrees) but should enter the common femoral artery over the femoral head and below the inguinal ligament. This access allows direct intervention for the infrainguinal vessels.

Infrainguinal Vessels

The arterial tree below the inguinal ligament begins with the common femoral artery. This vessel bifurcates early, at the level of the femoral head, into the profunda femoral artery and the superficial femoral artery (Fig. 74-9A). The superficial femoral artery is the principal vessel supplying the lower extremity. It courses anteriorly through the proximal 60% of its length and then begins to course posteriorly, entering the adductor canal (Hunter canal), a musculofascial canal bounded by the sartorius muscle anteriorly, the vastus medialis muscle laterally, and the adductor longus and magnus muscles posteriorly. This canal exits posteriorly, and the artery becomes the popliteal artery as it exits. The popliteal artery then terminates

FIGURE 74-9 ■ **A**, Digital subtraction angiography in the anteroposterior projection of the right common femoral artery. **B**, Infrapopliteal digital subtraction angiography in the anteroposterior projection. at the level of the tibial plateau into the anterior tibial artery and tibial-peroneal trunk vessels. The tibial-peroneal trunk then terminally bifurcates into the posterior tibial artery and the peroneal artery (see Fig. 74-9B). The posterior tibial and anterior tibial arteries usually are the principal vessels supplying the foot. The posterior tibial artery supplies the medial and lateral plantar vessels, and the anterior tibial artery supplies the dorsalis pedal artery. The distal plantar arteries, along with the dorsalis pedal artery, often communicate to form the plantar arch of the foot.

PERCUTANEOUS INTERVENTION

Thoracic and Abdominal Aorta

Intervention to the thoracic and abdominal aorta is usually performed for dissection, coarctation, or aneurysm and is discussed in full detail elsewhere in this text. Percutaneous intervention with stenting has become the primary method of correction of coarctation.⁵⁸⁻⁷⁰ Success rates for percutaneous interventions are 70% to 80% with a reduction of peak gradient less than 20 mm Hg. Most of the patients are seen within a pediatric population, and as such, adult disease is rarely seen as native coarctation. Percutaneous intervention to postoperative coarctation is feasible and limits the risk of a second open procedure (Fig. 74-10).⁶⁰

In general, there is a greater degree of atherosclerosis in the aorta after it crosses the diaphragm into the abdomen. The consequence of this is either lower extremity claudication or mesenteric ischemia. As disease in the abdominal aorta can lead to lower extremity claudication, it is a possible site of angioplasty and stent implantation

FIGURE 74-10 ■ Magnetic resonance angiographic anteroposterior view of hypoplastic aortic arch with a coarctation. The anatomy of this right-sided arch is as shown with the initial takeoff of the right carotid, then right subclavian (not shown), followed by left brachiocephalic off the descending aorta with intervening aortic-aortic graft. Inset: Completed stenting to the aortic-aortic graft.

FIGURE 74-11 ■ **A**, Anteroposterior and lateral digital subtraction angiograms of the distal abdominal aorta showing a distal lesion at the level of the inferior mesenteric artery. **B**, A widely patent vessel shown after angioplasty and stenting of the distal abdominal aorta.

(Fig. 74-11). Here, it is important to determine the significance of the lesion and the possibility of intervention. Once the characteristics of the lesion are defined and percutaneous intervention is pursued, the key element is to gain access in each femoral artery. One access point will serve as the primary intervention for the aorta, and the other will then cross the aortic stent, with further intervention to the iliac arteries performed in a “kissing” manner (see Fig. 74-11).

Mesenteric ischemia is somewhat uncommon, given the redundant blood supply to the intestine. If mesenteric ischemia is suspected and revascularization is warranted, a percutaneous procedure may afford less risk to the patient than that from an open surgical procedure. Stenting of the mesenteric vessels is performed usually from the common femoral artery. The long-term restenosis rate is approximately 10% to 15% after several years. Care should be taken in advancing the catheter or other devices through the lesion, because distal embolization can lead to further acute mesenteric ischemia.

Head and Neck Vessels

Whereas some patients have significant stenoses without any signs or symptoms, those patients who are symptomatic face a higher risk of future events.^{37,38} The North American Symptomatic Carotid Endarterectomy Trial

(NASCET) demonstrated that among patients with stroke, the incidence of recurrent ipsilateral stroke at 2 years was 26% for medical therapy as opposed to 9% with carotid endarterectomy (CEA) among patients with a lesion of more than 70% noted by angiography.³⁷ Similarly, the European Carotid Surgery Trial (ECST) demonstrated that in symptomatic patients with all levels of stenosis, patients treated with medical therapy had a 17% rate of stroke compared with 2.8% with surgical revascularization.³⁸ Thus, in symptomatic patients with high-grade stenoses (>70%), CEA appears to be beneficial.

Percutaneous transluminal angioplasty with stenting of the extracranial carotid artery has been performed for more than two decades (see Fig. 74-6B and C).⁷¹ The Global Utilization Report demonstrated the following incidence rates at 30 days: transient ischemic attack, 2.6%; minor stroke, 2.5%; major stroke, 1.4%; and mortality, 0.8%.⁷¹ The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) compared, in a nonrandomized trial, carotid percutaneous transluminal angioplasty and stenting with CEA.⁷² Overall, the combined stroke and mortality rate was similar between groups, at 10% and 9.9% by 30 days. At 3 years, outcomes remained similar.⁷³⁻⁷⁵

There have been two major trials comparing percutaneous techniques with CEA among high-risk⁷⁶ and average-risk patients.⁷⁷ The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) study was the first large-scale randomized trial comparing CEA with carotid artery stenting (CAS) with the use of distal protection devices.⁷⁶ SAPPHIRE was designed to test the hypothesis that CAS was not inferior to CEA. High-risk patients were defined as those with clinically significant cardiac disease, severe pulmonary disease, contralateral carotid occlusion or laryngeal nerve palsy, previous radical neck surgery, recurrent stenosis after CEA, or age greater than 80 years. Patients with symptomatic carotid artery disease required a stenosis of at least 50%, and those presenting with asymptomatic carotid disease required stenosis of at least 80%. The surgeons and the interventionists were compelled to agree that the patient was a suitable candidate for either procedure. The primary outcome was a composite of death, stroke, or myocardial infarction within 30 days or death or ipsilateral stroke between 30 days and 1 year. The primary endpoint occurred in 12.2% of patients who underwent CAS and 20.1% of patients who underwent CEA, which demonstrated noninferiority and nearly reached criteria for superiority ($P = 0.053$). Long-term efficacy and safety were evaluated at 3 years with a composite endpoint of death, stroke, or myocardial infarction in 24.6% of patients in the CAS group and 26.9% of patients in the CEA group—a nonsignificant difference.⁷⁸

Several randomized trials have challenged these results. In an attempt to extend the use of CAS to symptomatic patients of average surgical risk, the EVA-3S (Endarterectomy versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis) and SPACE (Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy) trials were undertaken.^{77,79}

To be enrolled in EVA-3S, patients had to have had a transient ischemic attack or stroke within the previous 120 days and an ipsilateral carotid stenosis of 60% to 99%.⁷⁷ The primary endpoint was the composite of stroke or death within 30 days after the procedure. The trial was ended prematurely after the enrollment of 527 patients because of safety concerns. Patients who underwent CAS had a 9.6% incidence of the primary endpoint, significantly higher than for patients who underwent CEA (3.9%). A major criticism of the trial was the lack of use of distal protection devices early in the trial, although the incidence of stroke even with the use of protection later in the trial was relatively high (7.9%) and still higher than the incidence among patients undergoing CEA. Furthermore, the use of several distal embolic devices with limited user experience was another significant criticism.

SPACE enrolled 1200 patients with a moderate stroke or transient ischemic attack within the previous 180 days.⁷⁹ The primary outcome—ipsilateral ischemic stroke or death through 30 days—was reached by 6.84% of patients in the CAS group and 6.34% of those in the CEA group, a difference that did not reach statistical significance for noninferiority. A major criticism of this trial was that distal protection devices were not mandated.⁸⁰ Furthermore, operators had limited experience with CAS.

Percutaneous outcomes can be improved with the use of distal protection devices (Fig. 74-12), such as the balloon occlusion GuardWire (PercuSurge, Sunnyvale, Calif.), the filter device AngioGuard (Cordis, Warren, N.J.), or the EPI filter (EPI, Inc., Boston, Mass.). Such distal protection devices have been shown to capture distal emboli that can be liberated with catheter manipulation, balloon inflations, or stenting in the carotid arteries (Fig. 74-13). The major difference is that the balloon occlusion device interrupts flow distally, whereas the

filter devices allow flow to continue but capture the debris.

The more recently completed CREST (Carotid Revascularization Endarterectomy versus Stenting Trial) trial was a large-scale randomized trial comparing traditional CEA with CAS with concurrent use of distal protection devices.⁸¹ The multicenter trial enrolled 2502 patients to assess CAS and CEA for both symptomatic and asymptomatic patients. Symptomatic patients were defined as those that had a transient ischemic attack, amaurosis fugax, or minor nondisabling stroke in the distribution of the study artery within 180 days of randomization, as well as stenosis of the carotid artery greater than 50% by angiography, greater than 70% by ultrasound, or greater than 70% by computed tomographic or magnetic resonance angiography if ultrasound was 50% to 69%. Asymptomatic patients were defined as having carotid stenosis of greater than 60% by angiography, greater than 70% by ultrasound, or greater than 80% by computed tomographic or magnetic resonance angiography if ultrasound was 50% to 69%. Patients with previous disabling stroke or chronic atrial fibrillation were excluded. Results suggested similar short-term and longer-term outcomes between CAS and CEA; however, there was higher stroke risk with CAS and higher myocardial infarction risk with CEA.

Renal Arteries

There are three major clinical trials evaluating the role of renal artery angioplasty or stent implantation among patients with documented renal artery stenosis and difficult-to-control hypertension.

Van Jaarsveld and colleagues⁵³ compared angioplasty alone with medical therapy in the control of hypertension in 106 patients with renal artery stenosis. Inclusion criteria included diastolic blood pressure of 95 mm Hg or higher despite the use of at least two antihypertensive agents, serum creatinine concentration of 1.7 mg/dL or less, and stenosis of 50% or more. More than 40% of patients in the drug therapy group underwent angioplasty in the 12-month follow-up period. Mean blood pressure did not differ significantly between the groups. At 3 months, patients in the angioplasty group were taking significantly fewer antihypertensive drugs, but this difference was not significant at 12 months. More patients in

FIGURE 74-12 ■ Distal protection devices. **A**, GuardWire (PercuSurge, Inc., Sunnyvale, Calif.). **B**, AngioGuard (Cordis, Warren, N.J.). **C**, EPI filter (EPI, Inc., Boston, Mass.).

FIGURE 74-13 ■ Distal macroscopic emboli captured with the GuardWire in an ulcerated left internal carotid lesion after predilation with angioplasty before stenting.

the angioplasty group had better blood pressure control, defined as a decrease of 10 mm Hg or more in diastolic blood pressure with no change in medications or a decrease in the number of drugs with no change in diastolic blood pressure. Median serum creatinine concentration was lower in the angioplasty group at 3 months but was not significantly different at 12 months. Major criticisms of the trial include its relatively short follow-up period and the high degree of crossover from the medical therapy group to the angioplasty group, thus limiting the true comparison of the treatment strategies. In addition, although a 50% stenosis was used as an inclusion criterion, pressure gradients across stenotic lesions in the renal vasculature may be more predictive of the pathologic effect of renal artery stenosis than the degree of angiographic stenosis.

A smaller prior study demonstrated a significant reduction in blood pressure compared with medical therapy for bilateral renal artery stenosis but not for unilateral stenosis,⁸² whereas a third study reported a decrease in the number of drugs needed to control hypertension.⁸³

Recent efforts have focused on the development of risk stratification tools to identify patients who would benefit from intervention. A normal resistive index (<80) is associated with a benefit from revascularization, whereas an index greater than 80 is not associated with a benefit from revascularization.⁵⁵ Although assessment of the pressure gradient is critical in selecting appropriate patients for revascularization, the presence of a catheter in a diseased ostium can falsely elevate the gradient. **Figure 74-14** shows a technique to ensure that the pressure gradient is not falsely elevated. As illustrated, when a catheter is placed across a lesion and the pressure difference is measured with the central aortic pressure, the small catheter contributes significantly to the overall gradient, which falsely elevates the true gradient as measured with a pressure wire alone. In this way, more physiologic gradients are measured and may help in revascularizing more appropriate lesions in the renal vasculature.

FIGURE 74-14 ■ Pressure measurements across a renal artery lesion with use of a 4 Fr multipurpose catheter and a 0.014-inch PressureWire (St. Jude Medical, Inc., St. Paul, MN) revealing a “false” gradient and a more physiologic gradient after the catheter is removed from the lesion.

The recently completed Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial enrolled 947 patients with atherosclerotic renal artery stenosis and either systolic hypertension while taking two or more antihypertensive drugs or chronic kidney disease. Patients were treated with either medical therapy and renal artery stenting or medical therapy alone. Median follow-up was 43 months. Participants were followed for the occurrence of adverse cardiovascular and renal events with a composite endpoint of death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive heart failure, progressive renal insufficiency, or the need for renal replacement therapy. Prior randomized studies, such as the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial⁸⁴ and the Stent Placement and Blood Pressure and Lipid-Lowering for the Prevention of Progression of Renal Dysfunction Caused by Atherosclerotic Ostial Stenosis of the Renal Artery (STAR) trial,⁸⁵ assessed the effect of stenting on kidney function and showed no significant difference, but both have been criticized for enrolling participants without clinically significant stenosis. Furthermore, neither of these studies was specifically designed to detect a benefit with regard to the incidence of clinical events. Nonetheless, the primary conclusion of the CORAL trial suggests that renal artery stenting did not confer a significant benefit with respect to the prevention of clinical events when added to comprehensive, multifactorial medical therapy in people with atherosclerotic renal artery stenosis and hypertension or chronic kidney disease.

Lower Extremity

Iliac Vessels

Once a lesion is identified on angiography, its functional significance and suitability for intervention can be further assessed with pressure wire measurements. A mean gradient greater than 10 mm Hg at rest or after induction of hyperemia following vasodilation (nitroglycerin or papaverine) is considered significant. The presence of symptoms, abnormal results of noninvasive studies, a significant stenosis on angiography, and a gradient of this magnitude indicate that the lesion is likely to merit revascularization.

Various revascularization techniques are available. Intravascular stenting has been associated with improved long-term patency compared with conventional balloon angioplasty,^{8,86-90} and clinical outcomes after stent placement appear to be similar to long-term outcomes after vascular surgery.^{32,91,92} Results from the STAG (Stents versus Angioplasty for the Treatment of Iliac Artery Occlusions) trial⁹³ was inconclusive regarding a difference in 1-year patency, although a reduction in perioperative complications with primary stenting versus angioplasty was observed. There are multiple stents currently approved for this location, including the Palmaz stent, Boston Scientific Express stent, and SMART stent. Recent studies continue to explore the efficacy of primary stenting for aortoiliac disease.

The advent and evolution of endovascular techniques has led to the use of an endovascular approach to

revascularization in this region when necessary, as with extensive or complex aortoiliac occlusive disease. The multicenter Covered Versus Balloon Expandable Stent Trial⁹⁴ recently suggested that covered stents can provide increased freedom from stenosis compared with bare metal stents at 12 and 18 months; this remains an area that bears further attention, and it will be addressed in the proposed Dutch Iliac Stent (DISCOVER) trial: covered balloon-expandable versus uncovered balloon-expandable stents in the common iliac artery.⁹⁵

Infrainguinal Vessels

Percutaneous interventions to the infrainguinal vessels are acutely successful in most patients, but balloon angioplasty alone remains associated with poor long-term patency.^{8,96-98} Stenting of the superficial femoral artery was not associated with improved patency in two small trials,^{99,100} but the introduction of nitinol stents has led to a significant reduction in restenosis and a significant improvement in walking distance compared with balloon angioplasty with provisional stent implantation in patients with infrainguinal disease.^{101,102} Schillinger and coworkers¹⁰¹ randomized 104 patients with severe claudication or chronic limb ischemia (Rutherford stages 3 to 5), a stenosis of 50% or more, a target lesion length of 3 cm or more, and at least one patent tibioperoneal runoff vessel to balloon angioplasty with provisional stent implantation for residual stenosis of 30% or more or the presence of flow-limiting dissection versus routine nitinol stent implantation. Average lesion length was approximately 13 cm, and 32% of patients in the angioplasty group underwent secondary stent implantation after failed angioplasty. Restenosis, defined as a stenosis of more than 50% on duplex ultrasonography, occurred in 37% of patients in the stent group and 63% of patients in the angioplasty group at 1 year. In addition, patients in the routine stent group were able to walk significantly farther on a treadmill at 6 and 12 months, and the ankle-brachial index was significantly better in the routine stent group at 12 months. The difference in restenosis rate remained significant at 2 years, although reintervention rates and clinical benefit were not significantly different (37.0% among patients undergoing balloon angioplasty and 53.8% among patients who underwent stent implantation; $P = 0.14$).¹⁰²

These results were not reproduced in a larger trial of patients with somewhat shorter lesions (1-10 cm to be enrolled; mean lesion length, 4.5 cm).¹⁰³ Restenosis rates at 12 months were 38.6% in the angioplasty group and 31.7% in the routine stent group, a nonsignificant difference.

In general, lesions in the superficial femoral artery are best treated percutaneously if the lesion is focal and less than 10 cm.¹⁰⁴⁻¹⁰⁶ As the lesion length increases, there is an increase in restenosis after angioplasty alone and, thus, stenting has become the default therapy for these lesion lengths.^{97,104-107} Of particular interest is the use of covered stents, such as the Viabahn stent (W.L. Gore & Associates, Newark, DE). This stent, approved by the U.S. Food and Drug Administration, has a technical success rate greater than 90%. Long-term efficacy was

demonstrated by Saxon and coworkers,¹⁰⁸ who randomized 200 patients with lesions of 13 cm or shorter to Viabahn stent implantation or angioplasty alone. At 12 months, patency rates were 65% in the stent group and 40% in the angioplasty group. Assisted primary vessel patency at 4 years has been reported to be 82%.¹⁰⁹ In a 3-year follow-up to the RESILIENT (Randomized Study Comparing the Edwards Self-Expanding LifeStent versus Angioplasty-alone In LESions INvolving The SFA and/or Proximal Popliteal Artery) trial,^{110,111} the authors sought to evaluate late outcomes of primary nitinol stenting for the treatment of femoropopliteal lesions up to 15 cm long. Nitinol stents were found to have superior short-term patency when compared to balloon angioplasty with 12-month freedom from target lesion revascularization at 87% for the stent group compared with 45% for the angioplasty group ($P < 0.0001$) and no difference in survival at 3 years (90% vs. 92%; $P = 0.71$) or major adverse events (75% vs. 75%; $P = 0.98$). Though Duplex ultrasound was not mandated after the first year of the study, freedom from target lesion revascularization at 3 years was significantly better in the stent group (76% vs. 42%; $P < 0.0001$), as was clinical success (63% vs. 18%; $P < 0.0001$). A recent study exploring the efficacy of primary stenting compared with percutaneous transluminal angiography with provisional stenting in popliteal artery lesions suggested equivalent 1-year patency.¹¹¹

In addition to traditional angioplasty and stent implantation, a number of alternative devices have been used to treat infrainguinal vessels, including atherectomy devices (both directional and rotational), atheroablative devices (e.g., laser), and specialized balloon catheters such as cryoplasty and drug-coated balloons.

The atheroablative technologies include the directional atherectomy catheters. This type of intervention, which was initially designed for use in the coronary circulation, has found a resurgence in the peripheral vasculature. Recently, the SilverHawk device from FoxHollow Technologies (Redwood City, Calif.) has been used in a nonrandomized registry of 84 patients.¹¹² De novo lesions had an 84% patency rate at 12 months and 73% patency at 18 months. Target vessel revascularization was required in 16% of lesions at 12 months.

Excimer laser technology can be used in many different anatomic locations and scenarios, including in-stent restenosis, and it can be used for patients with complex lesions as an adjunctive agent before stent implantation.^{113,114} Cryoplasty is another possible option that has had acute and short-term success in registry studies,¹¹⁵ although more rigorous evaluation with randomized clinical trials in longer lesions remains to be performed.

In superficial femoral artery lesions of moderate length, the use of a paclitaxel-coated balloon can also reduce the incidence of target vessel revascularization.^{116,117} With percutaneous intervention of the infrapopliteal arteries, patency is more difficult to maintain, given the small diameter of the vessels and their dynamic properties at the level of the lower extremity. Research continues with the goal of further elucidating optimal endovascular treatment in the infrainguinal vasculature based on lesion type and location, patient characteristics, and advances in endovascular technology.

Assessment and Management

Ascending Aorta and Arch Vessel Injuries

Descending Thoracic Aortic Injuries

Innominate and Arch Vessel Injuries

Conclusion

The heart is a vital organ, with its arch vessels encased in the chest cavity and protected by the manubrium, sternum, and rib cage. Injury to this organ can come from blunt trauma, which includes blunt cardiac injury, more commonly referred to as cardiac contusion, coronary artery injury, atrial/ventricular/valvular rupture, and aortic or arch vessel rupture. Injury can also result from penetrating trauma, with the right ventricle being most commonly injured, and ventricular septal defect being the most common intracardiac injury.

BLUNT CARDIAC INJURY

Historical Perspective

The first recorded cardiac chamber rupture and myocardial contusion were reported after autopsy findings as early as 1679 by Borch (as reported by Osborn¹) and in

1764 by Akenside,² respectively. In 1868, 76 cases reported by Fischer³ described 7 myocardial contusions and 69 traumatic ruptures. Experimental animal work and clinical autopsies by Bright and Beck⁴ have demonstrated that substantially severe forces are responsible for an entire range of cardiac trauma, whereas enormous force is required to rupture the heart. It is also observed that recovery is the general rule, and rupture is the exception. In 1958, a hallmark study by Parmley and colleagues⁵ of a large series of autopsy cases in the Armed Forces Institute of Pathology demonstrated that blunt traumatic heart injury had a 0.1% incidence, with the majority being isolated chamber ruptures (right then left ventricle, followed by right and left atria in decreasing order of occurrence) and some associated with combined aortic ruptures. Myocardial contusion or blunt cardiac injury, although rare, is the most common injury, whereas chamber or aortic rupture is usually fatal.

Mechanism, Pathophysiology, and Incidence

Mechanisms responsible for blunt cardiac injuries can occur from any deliverance of kinetic energy such as blast effect; direct crushing forces through the sternum or rib cage, which can also cause compression of heart against the vertebral column; and traction and torsion from deceleration forces owing to high-speed vehicular collisions and falls from great heights. A sudden rise of blood pressure from compression of the chest can injure the cardiac valves, cause a tear in the ventricular wall or septum, or result in chamber rupture.

These forces result in a continuous spectrum of cardiac injury, ranging from simple contusion to fatal cardiac chamber rupture, including *comotio cordis*, described as sudden cardiac arrest resultant from a sternal blow.⁶ Myocardial contusion, characterized by patchy areas of muscle necrosis and hemorrhagic infiltrate, can also impair ventricular contraction and lead to arrhythmia.

The true incidence of blunt cardiac injury remains expectedly difficult to measure, because the autopsy cases of fatal cardiac chamber rupture do not account for the majority of the blunt trauma cases, which go on to recover.

Clinical Presentation

The rupture of a cardiac chamber, coronary artery, or major intrapericardial vein or artery is usually fatal because of acute tamponade. The few patients who survive do so only because of tears in a cavity under low pressure.⁷⁻⁹ Myocardial contusion induces cardiac failure and arrhythmia that improve with time.¹⁰ Injury to a coronary artery can lead to immediate or delayed myocardial infarction with spasm or dissection of arterial wall.¹¹ Valvular tears resulting in aortic or mitral insufficiency can develop into cardiac failure within a few weeks, whereas tricuspid insufficiency can appear only after several years.¹²⁻¹⁴

Diagnosis

Paramount to an accurate diagnosis is the awareness from the history and physical findings of pain and tenderness over the anterior chest wall (which may be indistinguishable from a classic myocardial infarction), evidence of contusion, ecchymosis, anterior rib fractures, or flail chest.¹⁵ Many patients, however, do not exhibit characteristic symptoms.^{10,16} The presence of complex arrhythmias, subtle findings of a precordial thrill, or presence of a murmur may be all that is present at exam. Cardiac injury can also be reflected with hemodynamic instability marked by refractory hypotension and elevated venous pressure (external jugular vein distention may be absent in cases of severe blood loss) in the presence of cardiogenic shock.

Electrocardiography

Serial 12-lead electrocardiography has traditionally been used to screen patients to detect conduction disturbances resulting from blunt injury; however, there is no

pathognomonic finding that can reliably establish the diagnosis of blunt cardiac injury.¹⁵ Abnormalities range from sinus tachycardia, the most commonly encountered arrhythmia, to supraventricular arrhythmias, such as atrial flutter and atrial fibrillation, ventricular tachycardia, premature ventricular contractions, ventricular fibrillation, right bundle branch block with first-degree heart block or hemiblock, third degree heart block, and T-wave or ST-segment abnormalities.¹⁵ The presence of a normal electrocardiography in a patient who is hemodynamically stable warrants no further investigation.

Cardiac Enzymes and Troponins

The measurement of creatine phosphokinase with myocardial band has been shown to be unreliable,^{10,16-18} except for more specific muscle proteins including troponin (cTnT and cTnI).^{19,20} Combined abnormalities in electrocardiography and serial cTnI levels have been promising in showing increased sensitivity (62% if both positive) and specificity (100% if both negative),²¹ although another study has shown otherwise.²²

Admission electrocardiography and serial troponin levels should be obtained in patients suspected of blunt cardiac injury and followed by transthoracic echocardiography if clinically significant arrhythmias arise.

Two-Dimensional Transthoracic and Transesophageal Echocardiography

Bedside echocardiography has become an important diagnostic tool in trauma patients, detecting abnormalities in the heart (ventricular dyskinesia and valvular dysfunction), thoracic aorta, and presence of pericardial fluid.^{15,23-25} Patients are selected for this modality of examination after demonstration of abnormal electrocardiography and cardiac troponins.

Transthoracic echocardiography cannot be performed in 25% to 30% patients limited by chest wall edema, fractured ribs, and flail chest, whereas transesophageal echocardiography—a more useful adjunct in elucidating periaortic hematoma and other cardiac injuries—is limited by expertise and frequent requirement of intubation, and it cannot be performed in patients with facial or cervical trauma.^{23,24}

Radionuclide Scans

Technetium-99m pyrophosphate, thallium 201, single photon emission computed tomography (SPECT), and multiple gated acquisition scans (MUGA), all use the concept of radioactive substances binding to injured or infarcted sites in the myocardium. However, all have been abandoned secondary to low sensitivity and specificity in the detection of blunt cardiac injury.¹⁵

Spectrum of Blunt Cardiac Injury: Assessment and Management

Pericardial Injury

Blunt rupture of the pericardium can occur from a direct forceful impact to transmitted force from sudden

increased intra-abdominal pressure. Left pericardial tears parallel to the phrenic nerve are most common, followed by diaphragmatic, and right and mediastinal tears.⁷ The heart might eviscerate into the abdominal cavity or herniate through the pericardial sac with torsion of the great vessels. Patients who are stable are worked up and diagnosed with chest radiography, sonography, or computed tomography. Patients who are hemodynamically compromised clinically are treated with immediate surgical intervention (ER thoracotomy), at which time diagnosis is made and the heart is placed back into the pericardial sac, with closure of pericardium, with or without a Gore-Tex patch, to achieve a tension-free repair.

Valvular, Papillary Muscle, Chordae Tendineae, and Septal Injury

Rarely, valvular injuries occur, with the aortic valve being most commonly affected, followed by the mitral valve. Rapid displacement of blood secondary to crushing or compressive forces applied to the thoracic cage during ventricular diastole can lacerate cardiac valve leaflets (most common in the left coronary cusp, followed by the noncoronary cusp), papillary muscles, or chordae tendineae leading to valvular insufficiency.⁵ The classic signs of valvular insufficiency (new murmur, thrill or left ventricular dysfunction with cardiogenic shock, and associated pulmonary edema) may not be immediately recognized, secondary to other concomitant life-threatening injuries. In patients in stable condition, such findings should prompt further diagnostic studies, depending on the clinical status of the patient and prompt repair or replacement as necessary. Septal rupture is also uncommon, and prompt repair is necessary if the patient is symptomatic from significant left-to-right shunt resulting in pulmonary over circulation and right heart dysfunction.

Blunt Coronary Artery Injury

Injuries of the coronary arteries are extremely rare. The proximal right coronary and, more commonly, the left anterior descending artery (because of the location relative to the sternum) become injured with direct compression of sternum to coronary vessel or stretching of the vessel secondary to cardiac torsion, leading to thrombosis or intimal disruption. The result is no different than an acute myocardial infarction. Long-term sequelae of these injuries can also lead to ventricular aneurysm and eventual rupture, ventricular failure, production of emboli, or malignant arrhythmia.⁵

Cardiac Chamber Rupture

Cardiac chamber rupture is relatively uncommon, and only a small percentage of patients survive to reach the hospital.^{7,26,27} Several mechanisms for blunt cardiac rupture have been postulated,⁷ including direct precordial impacts, compression of heart between sternum and vertebral body, transmission of pressure via abdomen into the venous return rupturing particularly the atria, acceleration/deceleration injuries leading to tears of the heart at the attachment sites to the great vessels, blast

effects, and concussive blows thought to be fatal secondary to the production of malignant arrhythmias. Patients usually have persistent hypotension with evidence of pericardial tamponade. Diagnosis of widened mediastinum on chest radiograph or evidence of pericardial fluid from sonographic examination requires prompt intervention in the form of a subxyphoid window. For patients with cardiopulmonary arrest, emergency department (ED) thoracotomy may be the only chance, although the survival rate is dismal.

Myocardial Contusion

The terms *myocardial contusion* and *concussion* should be eliminated in favor of terminology that more precisely describes the injury.²⁸

- Blunt chest injury with electrocardiographic abnormality
- Blunt chest injury with free wall cardiac rupture
- Blunt chest injury with cardiac valve tear
- Blunt chest injury with septal defect
- Blunt chest injury with abnormal cardiac enzymes

We recommend that asymptomatic patients with anterior chest wall injuries not be admitted to the surgical intensive care unit for continuous electrocardiographic monitoring and serial determination of CPK-MB levels or be subjected to further cardiac imaging.

Conclusion

When blunt cardiac injury is suggested secondary to a good history and physical examination, further diagnostic testing with electrocardiographic monitoring and serial enzyme measurements should follow. Sonographic examination can elucidate the presence of pericardial fluid or cardiac or valvular dysfunction that might require prompt surgical intervention.

PENETRATING CARDIAC INJURY

Historical Perspective

In the past, cardiac injury has always resulted in death, as described in the death of Sarpedon from an impalement of a lance to the heart in *The Iliad*.²⁹

In 1761, Morgagni³⁰ described the compressive effects of blood on the heart. Larrey^{31,32} was credited for pioneering the technique of pericardial window. Duval³³ first described the median sternotomy incision, whereas Spangaro³⁴ first described the left anterolateral thoracotomy incision in 1906. In 1926, Beck described the Triad physiology of cardiac tamponade, and later described the repair technique of placing mattress sutures under the coronary vessels to spare ligation.^{35,36}

In 1946, Harken³⁷ described the removal of foreign bodies adjacent to the heart and great vessels. Beal³⁸⁻⁴¹ first described ED thoracotomy and, along with Cooley,⁴⁰ reported the potential benefits for cardiopulmonary bypass in the management of selected intracardiac injuries. Mattox⁴²⁻⁴⁴ further refined and championed ED thoracotomy and cardiorrhaphy, including emergency cardiopulmonary bypass by surgeons.

Incidence

Penetrating cardiac injuries are uncommon and are usually seen only in busy urban trauma centers. The true incidence is difficult to ascertain, as the numbers fluctuate with influence of violent crimes involving firearms or penetrating objects. In 1989, Mattox⁴⁵ reported on a 30-year experience at Ben Taub Hospital in Houston, Texas, of 539 cardiac injuries. Asensio^{46,47} reported a total of 165 cardiac injuries within a 3-year period at LAC/USC Medical Center in Los Angeles, California. Other major trauma centers reported significantly fewer injuries,⁴⁸ which again indicates the rarity.

Etiology

In the civilian arena, the majority of penetrating cardiac injuries results from gunshot wounds and stab wounds, with shotgun and impalement injuries accounting for a small percentage.

In the military arena, most soldiers do not survive the high-velocity automatic rifles encountered in battle. The majority of these patients have sustained injuries from fragments of grenades or shrapnel. Dominguez⁴⁹ described such injuries over a 6-month period in a small series in Baghdad, Iraq.

Clinical Presentation

Most cardiac injuries related to stab wounds are logically based on the trajectory of the insult. This is not so with gunshot wounds, which can injure the heart from precordial and extra-precordial entrance sites.⁵⁰ Hirshberg⁵¹ described 26% associated cardiac injuries in 82 patients presenting with combined thoracoabdominal injuries, whereas Asensio and colleagues⁵² reported 44% incidence of associated penetrating cardiac injuries in his series of 73 patients who sustained thoracoabdominal injuries.

Frank penetrating injuries to the cardiac chambers can lead to acute cardiac tamponade and death, or, similarly, hemorrhage through the lacerated pericardium into the hemithorax, with death as well. Patients that survive such injuries with intact pericardium to prevent fatal exsanguinating hemorrhage, allowing them to reach the trauma center alive, have varying degrees of hemodynamic instability^{46,47} secondary to pericardial tamponade. Interestingly, the Beck triad or Kussmaul sign is present in only 10% of patients⁵⁰ with pericardial tamponade.

Moreno and colleagues,⁵³ in a retrospective study of 100 patients with penetrating cardiac injuries, reported higher survival (77% vs. 11%) in patients with pericardial tamponade, and that right-side chamber injuries confer a higher survival of 79% versus 28% for left-side chamber injuries. Clarke and colleagues,⁵⁴ in a prospective review of 1862 patients over a 3-year period, demonstrated that penetrating thoracic trauma has a high mortality rate of 30% for stab wounds and 52% for gunshot wounds.

Diagnosis

Penetrating injuries, whether by stab wounds or gunshot wounds, should be highly suggestive of potential cardiac

injuries. Hemodynamically stable patients still require routine chest radiography, and a widened mediastinum should elicit caution for further workup. Sonography can determine the presence of pericardial fluid, which is supported by a physical examination that might detect the Beck triad or Kussmaul sign. Evidence of direct trajectory, where the heart is in the path, should require preparation for emergent bedside anterolateral thoracotomy should the patient acutely decompensate clinically.

Subxyphoid Pericardial Window

The reliability of this technique has been proved valuable in ascertaining penetrating cardiac injury.^{55,56} In addition, a transdiaphragmatic pericardial window⁵⁷ has been effectively described in cases of patients sustaining combined thoracoabdominal injuries and cardiac injury needing to be investigated. This technique is also valuable when two-dimensional echocardiography (applied in focused abdominal sonography in trauma) is not available.

Two-Dimensional Echocardiography

Echocardiography has become the gold standard in diagnosis and evaluation of patients with penetrating thoracic injury. It is fast, painless, reproducible, and easily repeated.^{50,57,58} The procedure has 96% accuracy and 97% specificity.⁵⁹ Furthermore, it can be used to delineate intramyocardial foreign bodies versus missiles located within the cardiac chamber.^{60,61}

Management

In patients with penetrating cardiac injury, the majority would have a fatal outcome, no matter the prehospital intervention. In the select group that is still stable enough for transport to the trauma center, time is of utmost importance. This prehospital course is marked by certain surrogate parameters for either improved or dire prognosis.

Under no circumstances should emergency medical personnel delay transport by inserting intravenous lines; this should occur during transport. Concomitant notification of the trauma center to activate the trauma team is also of paramount importance.⁵⁰ Gervin and Fisher⁶² demonstrated a survival advantage if transport to the trauma center was within 9 minutes, whereas all patients with transport time greater than 25 minutes died. Mattox and Feliciano⁶³ found no survivors in 100 patients who received external cardiac compression for more than 3 minutes in the prehospital period. Lorenz and colleagues⁶⁴ noted better survival if patients had systolic blood pressures of 60 mm Hg or greater in the field and upon arrival in the ED. Durham and colleagues⁶⁵ linked prehospital intubation to better tolerance and successful prolongation with prehospital cardiopulmonary resuscitation of less than 5 minutes.

Upon arrival to the ED, the trauma team should be ready to perform advanced trauma life support protocol.⁶⁶ Patients are usually hemodynamically stable at presentation, allowing for expedited yet detailed workup. Another group will be unstable but respond to fluid resuscitation, allowing time to proceed to the operating

room for life-saving surgery. The last group will go into cardiopulmonary arrest requiring ED thoracotomy.^{46,47,50,67} ED thoracotomy, if performed under strict indications for cardiac injuries, has been shown to improve survival rate as much as 31%.⁶⁸ However, patients sustaining multiple cardiac or great vessel gunshot wounds were nearly unsalvageable with ED thoracotomy.⁶⁹

Techniques for Cardiac Injury Repair

Incisions

Median sternotomy, as well as the anterolateral thoracotomy, are the two main incisions of choice. The former is acceptable in patients who are treated for penetrating low anterior chest injuries and who arrive in some degree of hemodynamic instability, but are stable enough for sonographic and chest radiography workup for occult cardiac injuries. The latter is the incision of choice in the management of patients who arrive in extremis. This incision is also used in the ED for emergent resuscitative purposes.^{46,47,50,67,70} The anterolateral thoracotomy can also be extended into the right chest to provide for optimal exposure of the mediastinum and both hemithoracic cavities as necessary.

Adjunct Maneuvers

Exposure of the heart to repair posterior injuries can be accomplished a number of ways. The first step is to place the patient in acute Trendelenburg position, which will optimize the following described strategies for further exposure of the posterior side of the heart. Pledgeted sutures can be placed on the apex of the heart with the sutures cut long, to retract the apex slowly and superiorly to gain access to the posterior injury. A Satinsky clamp can also be used on the right ventricular angle to achieve the same exposure.⁷¹ Sequential placement of folded wet towels behind the heart will gradually lift the heart without causing it to go into arrhythmia and will provide exposure to the posterior injury as well. Stabilizing devices can also be used to provide exposure and steady placement of repair stitches on laceration injuries to the heart without causing further tearing.

Total inflow occlusion of the heart can be performed by placing clamps on the intrapericardial location to isolate and repair injuries at the level of atriocaval junction. The heart will frequently fibrillate, requiring paddle defibrillation and pharmacologic intervention.^{50,70}

Repair of Atrial Injuries

Right atrial injuries can usually be controlled with a Satinsky clamp followed by repair using 4-0 nonpledgeted polypropylene monofilament sutures. The atrium is thin walled and easily torn; therefore, caution and gentle traction aid in repair without further tearing.

Repair of Ventricular Injuries

Blast injuries resulting from gunshots, unlike a stab incision to the ventricle, can make the epicardium and

myocardium more friable and unforgiving with standard suture repair. Coupled with high-pressured bleeding, particularly from a left ventricle injury and tachycardia, the repair can be challenging; 2-0, 3-0, or 4-0 polypropylene with pledgeted sutures should be used and placed in a horizontal mattress fashion. Commercial brand fibrin sealant can be used to reinforce the suture line if necessary.

Coronary Artery Injuries

Direct coronary artery injury can be challenging to repair. Proximal injuries require bypass, especially if there is gross evidence of cardiac ventricular dysfunction. Distal coronary artery injuries, particularly the distal third of the vessel being injured or lacerated, might not require bypass if the heart remains without ventricular dysfunction and tolerates ligation.

Pericoronary artery injuries to the heart with significant bleeding can be managed with horizontal mattress sutures underneath the coronary vessel for safe repair, taking care not to narrow or occlude the coronary artery in the process.^{50,67,72}

Complex and Combined Injuries

Complex and combined injuries can be defined as penetrating cardiac injury in addition to associated thoracic, thoracic-vascular, neck, abdominal, abdominal-vascular, or peripheral vascular injuries. Priority should be given to treatment of injury with the greatest risk of blood loss or being life-threatening.^{50,67,73-75}

Wall and colleagues⁷⁶ described complex cardiac injuries as those beyond lacerations of the myocardium. These injuries often include concomitant coronary artery injuries, cardiac valvular injuries, intracardiac fistulas, and ventricular false aneurysms and coronary sinus injuries. These injuries can be addressed by the cardiac surgeon once the other life-threatening injuries are temporized and addressed.

Conclusion

Penetrating cardiac injury should prompt a comprehensive workup, with a sonographic examination being useful to diagnose the presence of pericardial fluid. Workup can be more extensive in a hemodynamically stable patient with computed tomography (CT) studies. Anterolateral thoracotomy can be used in the emergent setting to cross-clamp the descending aorta and to perform necessary cardiac repairs. Median sternotomy can be used in a patient in stable condition with identified cardiac injuries repaired.

THORACIC AORTA AND ARCH VESSEL INJURIES

Mechanisms and Types of Injury

Penetrating trauma to the thoracic aorta or its arch vessels can lead to immediate exsanguination or a pattern

of injury, much like blunt trauma to the vessels, which can include pseudoaneurysm, partial transection with resultant intimal flap, intimal dissection, thrombosis, and propagation.

Blunt trauma is more interesting from the standpoint that different forces can create injury to the thoracic aorta and its arch vessels. Traction and deceleration forces are classic mechanisms of injury to the thoracic vessels. Vertical deceleration can acutely strain the ascending aorta and innominate artery, as the heart is being displaced caudally and into the left pleural cavity by its natural lay in the mediastinum.^{77,78} Horizontal deceleration acutely strains the aortic isthmus,⁷⁷ whereas sudden extension of the neck or traction at the shoulder will stretch and strain the arch vessels to produce a spectrum of injuries to the vessels including intimal tear, disruption of the media, and complete rupture of the arterial wall.^{77,78} These injuries may again lead to intimal dissection, thrombosis, and propagation or development of pseudoaneurysm.

Natural History

Vessel injuries that involve mural hematoma or limited intimal flap have a benign course and frequently resolve with time.⁷⁹ However, pseudoaneurysms, including small ones, have an insidious course; they tend to expand, compress surrounding structures, and fistulize to surrounding organs, with eventual rupture.^{78,79}

Arch vessel injuries from penetrating or blunt trauma with partial transection bleed and are contained by the local tissues.^{80,81} Avulsions of the arch vessel at the take-off from the arch can bleed into the pericardial or pleural cavity. Acute occlusion of the subclavian artery rarely leads to limb ischemia because of the rich collateral network; however, acute occlusion of the common carotid artery can result in brain ischemia.^{82,83}

Free rupture of the thoracic aorta by penetrating or blunt trauma leads to immediate death in 75% to 90% of cases. Of the few who survive with containment of pseudoaneurysm by the parietal pleura, statistically 8% to 13% will rupture within the first hour of admission, 30% will rupture within 24 hours, and 50% will rupture within 1 week.^{84,85}

Diagnosis

A good history and physical examination will capture many of the injuries of the thoracic vessels. A high-speed head-on collision, fall from great height, ejection from a vehicle, death of another person in the same motor vehicle crash, presence of a seatbelt sign—all should alert one to the possibility of deceleration injury to the thoracic vessels. Penetrating trauma to the base of the neck and chest cavity will lead to the suggestion of injury to the vessels from its trajectory. Gunshot wounds should lead one to suspect any type of injury, which is possible from the ricochet of the bullet on entrance into the chest cavity.

Clinical presentation of arch vessel injury can include cervical or supraclavicular hematoma, bruit, or diminished peripheral pulse.⁸⁰ An aortic isthmus injury can produce decreased blood pressure in the left arm,

although this occurs in only 5% of patients.^{86,87} Brachial plexus injury is usually associated with subclavian artery injury as well.^{81,82} Coma or hemistroke can occur with common carotid injury.^{80,82,84}

Radiographic studies should begin with chest radiography, which in the presence of an injury would typically show a widened mediastinum, blunting of the aortic knob, and enlargement of paratracheal stripe.⁸⁶ Helical CT can detect arterial lesions and has excellent accuracy.⁸⁸ The gold standard is aortic angiography, which provides imaging of the entire thoracic aorta and arch vessels, but this takes time and requires a patient in relatively stable condition.⁸⁷ Transesophageal echocardiography can evaluate the aortic isthmus effectively, but it is less effective in evaluating the distal ascending aorta or arch vessels secondary to interference of the respiratory tract.⁸⁹ There has been a shift in widespread use of CT angiography, and almost complete elimination of aortography and transesophageal echocardiography over the last 10 years.⁹⁰

Assessment and Management

With a normal chest radiograph, the risk of thoracic aortic injury is low; however, if given the history of great fall or deceleration accident, a CT scan would be appropriate. Normal CT results almost certainly rule out injury to the aorta and obviate the need for further investigation. If the mediastinum is enlarged, then the diagnosis of thoracic vessel injury should be determined by angiography because both CT and transesophageal echocardiography can miss certain vascular injuries, especially the arch vessels.⁸⁹

Medical treatment especially aimed at treatment of suspected or identified aortic tear should address prevention of hypertension and pain. Short-acting β -blockers reduce blood pressure, the force of arterial upstroke, and heart rate, with good effect on reducing stress (anti-impulse) on the aortic wall.^{84,91}

Surgery is indicated for repair of most diagnosed thoracic artery lesions.^{87,92} Arch vessels can usually be repaired without circulatory support or arterial shunting. Repair of the aortic isthmus can be done with or without partial circulatory support.⁸⁵ Repair of the ascending aorta and arch usually necessitates full circulatory support with extracorporeal circulation, and possibly with hypothermic circulatory arrest.⁹³

Ascending Aorta and Arch Vessel Injuries

Injuries to ascending aorta or to arch vessels are best repaired by the cardiac surgeon for definitive repair. Isolated ascending aortic injury can be repaired with cardiopulmonary bypass and graft interposition to replace the area of injury. Care should be taken to address intimal dissection—the dissection plane should be obliterated with a combination of felt pledgets and biogluue.

Arch injury can also require circulatory arrest with isolated right subclavian artery (advantage of antegrade cerebral perfusion) or femoral artery cannulation with femoral-atrial venous cannulation bypass to repair the injury with interposition graft successfully.

Descending Thoracic Aortic Injuries

The approach is optimized with a left thoracotomy incision. Identification of the left subclavian artery, left recurrent laryngeal nerve, and left common carotid artery is prudent to allow for safe proximal aortic control, as the aortic clamp is placed between the left common carotid artery and left subclavian artery, avoiding injury to the recurrent laryngeal nerve. Distal aortic control requires a clamp to be placed distal to the area of injury.

Left heart bypass or clamp-and-sew technique can be used to repair the injury, usually with an interposition graft versus primary repair of the injured descending aorta; this carries a significant risk of spinal cord ischemic injury as well.

Recent improvements in technology have allowed the placement of an aortic endograft stent across the injury, which significantly decreases the risk of spinal cord ischemia.⁹⁴ However, long-term follow-up needs to be performed and outcome assessed in the otherwise young, healthy population with descending aortic injury that would have undergone an open repair.

Innominate and Arch Vessel Injuries

The approach to innominate or arch vessel injury is via median sternotomy with or without cardiopulmonary bypass. Debranching repair can be performed with partial aortic cross-clamp to isolate the base of the arch vessel, which can then be divided, with the base oversewn. The distal arch vessel can then be sewn to an interposition graft that is reattached to the ascending aorta with partial aortic cross-clamp as well.

Conclusion

Blunt or penetrating injuries to the chest may involve the thoracic aorta and great vessels. Successful repair is determined by complete proximal and distal control of the injury with or without cardiopulmonary bypass. Interposition graft is usually used, although primary repair is equally optimal if the tissue reapproximates well. Intimal dissection should be checked during repair and then treated. Aortic endograft stent repair is gaining notice, and it should be part of the armamentarium of the surgeon.

CHOICE OF VALVE REPLACEMENT

THE IDEAL VALVE

Many acceptable substitutes exist today for the replacement of diseased human heart valves. The ideal valvular prosthesis as described by Harken¹ remains the gold standard of cardiac surgery. According to Harken this valve would be durable, with a longevity approaching that of a native valve, thrombogenicity would not be a factor, and therefore no need for supplemental anticoagulation would exist. In addition, this valve would have no inherent gradient, thus allowing unimpeded outflow, and could be implanted with ease while being readily available. Lastly, the valve could grow commensurate with that of the recipient. While the technology of valve prostheses has evolved considerably over the past six decades, this lofty goal has yet to be met.

HISTORY

The first human heart valve operation was a digital valvotomy of a stenotic aortic valve performed by Tuffier in 1914. Cutler, Souttar, Brock, Swan, and Harken refined valvotomies and commissurotomies in the ensuing decades; however, the limited success of these techniques brought to light the need for an effective means of replacing the entire valve. The first step in the evolution of this technology came in 1950 when Hufnagel developed a ball valve that he placed in the descending thoracic aorta of a patient with severe aortic insufficiency.² In 1956, Murray implanted an aortic homograft in the descending thoracic aorta of a patient with severe aortic insufficiency.³ The

introduction of cardiopulmonary bypass opened the era of implanting valve prostheses in their native positions. In 1960, Braunwald and Harken successfully replaced the mitral and aortic valves using valves made of polyurethane.⁴ In 1961 Albert Starr, a surgeon, and Lowell Edwards, an engineer, developed a caged ball valve that resulted in acceptable long-term survival.⁵ Despite their success, the high profile of caged ball valves made implantation in patients with small ventricles and small aortic roots difficult. These valves also had inherently high gradients along with less favorable thromboembolic profiles, making them less desirable as new prostheses were introduced. Edwards Lifesciences (Irvine, CA) discontinued production of the Starr-Edwards valve in 2007.

The next generation of valve prosthesis used a tilting disc that would pivot into an open and close position according to the flow of blood across the valve. Wada was the first to introduce these tilting disc valves in 1966.⁶ The Lillehei-Kaster valve, introduced in 1967, was a hingeless valve with a freely rotating pivoting disc retained by struts. Björk, working with Shiley Laboratories, developed a similar version of a hingeless pivoting disc valve in 1969. Although the hemodynamic profile was improved relative to the caged ball valves, these early pivoting valves were subject to occasional thrombosis. The 60-degree convexoconcave Björk-Shiley valve was prone to catastrophic structural failure secondary to fracture of its welded struts, allowing escape of the occluder disc.⁷

Seeking to improve on the durability and thrombogenicity problems of these early pivoting disc valves, Hall, Woien, Kaster, and the Medtronic Corporation (Minneapolis, MN) introduced the Medtronic-Hall valve in

1977. The valve housing was constructed from one piece of titanium alloy with no introduced welds or bends. The round central disc was made from tungsten-impregnated graphite with a pyrolytic carbon coating, and it had a central hole that allowed the disc to be retained by a curved central guide strut that was part of the housing. Valve washing was improved by a relatively larger minor orifice and a disc that lifted out of the housing and rotated with opening. It had a moderately high profile in the open position and a low transvalvular gradient. Occluder impingement was possible because its position at the equator of the valve housing made it susceptible to obstruction from retained valve elements, sutures cut too long, or pannus. Loss of structural integrity, however, was never reported. The valve could be rotated after implantation to achieve the desired orientation. Several studies reported a low incidence of valve-related morbidity and mortality.^{8,9} Svennevig and colleagues reported a 25-year experience of 816 patients that underwent an aortic valve replacement using the Medtronic-Hall valve.¹⁰ Linearized rates of thrombotic complications, warfarin-related bleeding, and endocarditis were 1.5%, 0.7%, and 0.16% per patient-year, respectively. Valve thrombosis was seen in only four patients. Seventy-nine percent of the patients were in New York Heart Association classes I or II. Despite these outcomes, Medtronic discontinued manufacturing the valve in September of 2009, removing the last of the tilting disc prosthesis available for clinical use.

The next step in the evolution of valve prostheses came in 1977 when St. Jude Medical (Minneapolis, MN) introduced a bileaflet mechanical valve.¹¹ The design has undergone several refinements since its introduction. Its advantage over the caged ball valves or the tilting disc valves are its greater effective orifice area and therefore improved gradients, along with reduced thrombogenicity.

In light of the thrombogenic potential of mechanical valves and the need for lifelong anticoagulation, development of tissue-based valves was undertaken in parallel with mechanical prosthesis. In 1962, Ross reported the use of aortic homografts for aortic valve replacement (AVR) and subsequently developed the Ross procedure, which uses a pulmonary autograft for replacement of the aortic valve.¹² In 1969, Carpentier and Hancock developed the first porcine xenografts,¹³ and Ionescu developed the first glutaraldehyde-preserved bovine pericardial valve in 1971.¹⁴ Limited long-term durability secondary to leaflet calcification and subsequent valve failure plagued the early generation of bioprostheses. Significant progress has been made in improving the durability of these valves through improved fixation strategies and overall valve design. State-of-the-art anticalcification methods are now being used in an effort to improve valve longevity. Given the inherent gradients with stented bioprostheses, stentless xenografts were introduced in 1986, and they have remained an effective option for a tissue-based prosthesis.¹⁵

MORBIDITY AND MORTALITY GUIDELINES FOR VALVE OPERATIONS

Clinical studies are crucial for determining outcomes after cardiac valve operations and precise definitions of

outcomes are critical in comparing valve prostheses. To address this need, the councils of the Society of Thoracic Surgeons (STS) and the American Association of Thoracic Surgery (AATS) formulated the Ad Hoc Liaison Committee for Standardizing Definitions of Prosthetic Heart Valve Morbidity. The initial report of this committee was issued in 1988¹⁶ with an update in 1996.¹⁷ The report strictly defines types of morbidity and mortality that can occur after valvular surgery. An understanding of these definitions is crucial for interpreting studies dealing with valvular prostheses.

The guidelines distinguish two types of mortality: hospital mortality and 30-day mortality. *Hospital mortality* refers to death occurring at any time before discharge during a patient's initial hospitalization. Thirty-day mortality, also referred to as *operative mortality*, is death that occurs at any time or place within 30 days of the procedure. There are several precise definitions of valve-related morbidity. *Structural valve deterioration* (SVD) refers to "any change in function of an operated valve resulting from an intrinsic abnormality of the valve that causes stenosis or regurgitation."¹⁷ It includes "changes intrinsic to the valve, such as wear, fracture, poppet escape, calcification, leaflet tear, stent creep and suture line disruption of components ... of an operated valve."¹⁷ Thrombotic or infectious causes of valve dysfunction are not included.

Nonstructural dysfunction includes nonthrombotic and noninfectious causes of valvular stenosis or regurgitation that are not intrinsic to the valve itself. "Examples ... include entrapment by pannus, tissue, or suture; paravalvular leak; inappropriate sizing or positioning; residual leak or obstruction from valve implantation or repair; and clinically important hemolytic anemia."¹⁷ Morbid events are often reported as the composite linearized rate, or the number of events divided by the number of patient-years of follow-up (events/patient-years). The composite linearized rate for nonstructural dysfunction of the commonly available mechanical valves is 0.2 to 0.8 (events/patient-years) for the aortic position and 0.3 to 1.4 (events/patient-years) for the mitral position.⁹ Valve thrombosis is defined as thrombus in or about the valve that is not associated with infection and that interferes with valve function or obstructs blood flow through the valve. The composite linearized rate of thrombosis of mechanical valves is 0 to 0.2 (events/patient-years) in the aortic position and 0.4 to 0.8 (events/patient-years) for the mitral position.⁹

Embolism refers to any embolic event not associated with endocarditis that occurs after the immediate perioperative period and after the emergence from anesthesia. Embolic events are further delineated into neurologic events and peripheral embolic events. The composite linearized rate of thromboembolism ranges from 1.4 to 2.5 (events/patient-years) for the aortic position and 1.8 to 3.6 (events/patient-years) for the mitral position.⁹

A bleeding event refers to any clinically significant bleed requiring hospitalization or transfusion or causing death. A patient does not have to be taking an anticoagulant to sustain a bleeding event. Composite linearized rates vary from 0.8 to 2.5 (events/patient-years) for the aortic position and 1.2 to 2.2 (events/patient-years) for the mitral position.⁹

Endocarditis involving an operated valve is designated operated valvular endocarditis. “Morbidity associated with active infection, such as valve-thrombosis, thrombotic embolus, bleeding event, or paravalvular leak, is included under this category and is not included in other categories of morbidity.”¹⁷ Composite linearized rates for prosthetic valve endocarditis range from 0.4 to 0.7 (events/patient-years) for both the aortic and mitral positions.

Consequences of morbid events are also defined by the guidelines. A reoperation is any operation on “a previously operated valve.”¹⁷ The composite linearized rate for reoperation ranges from 0.3 to 1.8 (events/patient-years) for the aortic position and 0.6 to 1.6 (events/patient-years) for the mitral position.⁹

Valve-related mortality is any death after a valve operation caused by a morbid event that is not related to progressive heart failure in patients with functioning valves. Unexplained deaths are just that, and they should be listed as such. Cardiac deaths include valve-related deaths, sudden deaths, and non-valve-related cardiac deaths. *Total deaths* refer to any and all deaths after a valve operation. *Permanent valve-related impairment* refers to any “permanent neurologic or functions deficit” caused by a morbid event.¹⁷

PROSTHETIC HEART VALVES

The following section lists and describes prosthetic heart valves available worldwide. The valves are grouped

according to their structural type (i.e., mechanical vs. bioprosthetic), manufacturer, and design specifications. The order in which they appear in no way delineates a preference by the authors. For a summary of clinically available valves, implantation positions, and sizes please see [Tables 76-1 and 76-2](#).

Mechanical Valves

Bileaflet Prostheses

Medtronic. The Medtronic Open Pivot Mechanical Heart Valve ([Fig. 76-1A](#)) is a bileaflet valve that was originally developed and owned by ATS Medical, Inc. (Minneapolis, MN). The valve is made of a solid pyrolytic carbon orifice and a titanium strengthening band that provides it with added durability. Its unique design eliminates shallow recesses in the hinge area where clots may form. These design features lead to a continuous gentle flow of blood across the valve, resulting in low levels of clotting while helping to prevent damage to blood cells. Furthermore, with the Open Pivot design, the unimpeded flow of blood provides for a continuous passive washing of the valve. Within the Open Pivot Series, there are three subtypes, each geared toward different potential clinical needs. The AP360 is an aortic valve prosthesis with a supra-annular flanged cuff configuration designed for added flexibility and conformability, and it is available in sizes from 16 to 26 mm. The AP valve has a supra-annular compact cuff configuration for ease of suturing and overall conformability. The valve can be placed in either the

RSR, Reduced sewing ring.

aortic or mitral position and is also available in sizes from 16 to 26 mm. The Standard valve is designed for intra-annular placement and has a generous and compliant cuff. The valve is available in sizes from 19 to 31 mm in the aortic position and 25 to 33 mm in the mitral position. All the Open Pivot valves are rotatable in situ.

Several studies have demonstrated good hemodynamics and an overall low complication rate with these valves.¹⁸⁻²¹ Bernet and colleagues²² reported their outcomes for a series of 1161 patients that received either the SJM valve or the Open Pivot Mechanical Valve. Cumulative survival and freedom from valve-related

mortality at 10 years for the SJM valve and Open Pivot Mechanical Valve were 66% ± 3% versus 68% ± 5% ($P = 0.84$) and 96% ± 1% versus 97% ± 1% ($P = 0.36$), respectively. No structural valve failure was encountered for both valve types. The linearized rates for valve-related adverse events for the SJM valve and Open Pivot Mechanical Valve were, respectively: thromboembolism, 0.9% and 1.1% per patient-year; major bleeding requiring transfusion, 0.3% and 0.5% per patient-year; prosthetic endocarditis, 0.03% and 0.1% per patient-year; paravalvular leak, 0.1% and 0.6% per patient-year.²²

St. Jude Medical. The St. Jude Medical (SJM) Standard valve prosthesis was approved by the U.S. Food and Drug Administration (FDA) in 1977, and more than 2.3 million valves have been implanted worldwide. The SJM leaflets and ring orifice are constructed with pyrolytic carbon and are highly durable. The 85-degree leaflet opening angle provides improved laminar flow and reduces turbulence. The Hemodynamic Plus (HP) series was developed to address the inherent gradient in smaller valves and the potential for patient-prosthesis mismatch. With the small annulus in mind, the sewing cuff was reduced and redesigned to allow supra-annular placement of the valve, leading to an increased effective orifice area (EOA). The Masters Series was later introduced, providing the ability to rotate the valve to the desired orientation after implantation. The Standard and HP valves are offered only within the Masters Series. The available Standard valve sizes are 19 to 31 mm for the aortic position and 19 to 33 mm for the mitral position, whereas the available HP valve sizes are 17 to 27 mm for both the aortic and mitral positions. The Regent valve (see Fig. 76-1B) is the most recent evolution of the bileaflet design, developed to improve hemodynamic performance. In addition to a supra-annular cuff, the carbon rim was shifted to the supra-annular position. As with the Masters Series it is fully rotatable as well. This redesign allows the valve to achieve an increased EOA and an up to 84%

orifice-to-annulus ratio. The Regent valve is available only for the aortic position and for sizes ranging from 19 to 27 mm.

Several reports have documented the outcomes of the various valve series produced by SJM.²²⁻²⁷ Tool and colleagues²⁸ reported their 25-year experience in which 946 valve recipients were followed prospectively at 12-month intervals from 1979 to 2007. The series included implants using all SJM designs, with the original Standard valve being the most widely used. Among aortic valve recipients, 25-year freedom from reoperation, thromboembolism, bleeding, and endocarditis was $90\% \pm 2\%$, $69\% \pm 5\%$, $67\% \pm 3\%$, and $92\% \pm 3\%$, respectively. Among mitral valve recipients, 25-year freedom from reoperation, thromboembolism, bleeding, and endocarditis was $81\% \pm 10\%$, $52\% \pm 8\%$, $64\% \pm 6\%$, and $97\% \pm 1\%$, respectively. Freedom from valve-related mortality was $66\% \pm 8\%$ and $87 \pm 3\%$ for aortic and mitral valve replacement (MVR), respectively.²⁸

Head-to-head comparisons between the standard and HP designs have also been reported. Vitale and colleagues²⁹ reported results from the Multicenter Study Group for the SJM HP aortic valve prosthesis. This prospective randomized study included 140 patients with 21- and 23-mm-annulus diameters and who received either the SJM Standard valve or the HP valve. Postoperatively and at 6 months, echocardiographic

hemodynamic variables such as ejection fraction, cardiac output, peak gradient, mean gradient, EOA, indexed EOA (iEOA), and performance index were calculated. Decreased peak and mean gradients and increased EOA, iEOA, and performance indexes were found for the HP valve. The authors concluded that use of the HP valve allows implantation of smaller prostheses without patient-prosthesis mismatch (PPM) and with avoidance of the additional morbidity associated with root enlargement procedures.²⁹ Ismeno and colleagues³⁰ similarly reported their results comparing the 19-mm standard and HP valve in the aortic position after 5 years. Those who received the HP valve had statistically better hemodynamics with lower peak and mean gradients and larger EOAs. There was no difference, however, in terms of 5-year survival, late complications, or left ventricular mass reduction between the two groups.³⁰

The Regent valve has also demonstrated good *in vivo* hemodynamics and clinical outcomes. Bach and colleagues³¹ reported the results of a multicenter study from North America and Europe of 361 patients that underwent aortic valve replacement using the Regent valve. The mean gradient at 6 months was 9.7 ± 5.3 mm Hg for the 19-mm valve, with the larger valves having progressively lower gradients. The iEOA was equal to or greater than $1.0 \text{ cm}^2/\text{m}^2$ for all valve sizes and left ventricular mass index decreased significantly between early postoperative ($165.9 \pm 57.1 \text{ g/m}^2$) and 6-month follow-up ($137.9 \pm 41.0 \text{ g/m}^2$; $P < 0.0001$).³¹

Sorin Group. The Sorin Group (Milan, Italy) manufactures two mechanical valve series: the Bicarbon Product Line, developed internally by Sorin, and the CarboMedics Product Line, acquired through the purchase of Sulzer CarboMedics. Within each series there are multiple subtypes geared toward a variety of clinical needs. As a whole, the mechanical valves in their catalog are bileaflet. For Bicarbon, the leaflets are constructed from pyrolytic carbon deposited on a graphite substrate and a housing made of titanium alloy treated with a proprietary Carbofilm coating for enhanced hemo-biocompatibility. For the CarboMedics valve the leaflets are constructed from pyrolytic carbon deposited on a graphite substrate, like those of the Bicarbon valve. The housing of the CarboMedics valve is fabricated from nonsubstrated pure pyrolytic carbon reinforced with a titanium reinforcing ring.

The Bicarbon series features the Fitline valve, which is designed for intra-annular implantation and is available for both aortic and mitral valve replacement. It will fit annular sizes of 19 to 31 mm for the aortic position and 19 to 33 mm for the mitral position. The Bicarbon Overline maintains the same design as the Fitline while improving hemodynamics through its supra-annular seating and 100% orifice-to-annulus ratio. These design features make the valve suitable for small annuli and create the potential benefit of decreasing the need for annulus enlargement. The Overline valve is available only for the aortic position and for 16- to 24-mm sizes. The Bicarbon Slimline is designed for partial supra-annular seating and therefore improved hemodynamics, while maintaining the same design features as the Fitline. The Slimline valve is available only for the aortic position

and for sizes from 17 to 27 mm. All the Bicarbon valves are rotatable *in situ* and are available only outside the United States.

The CarboMedics mechanical valve series has six different valve designs within its portfolio. The Top Hat valve (see Fig. 76-1C) is designed for supra-annular implantation in the aortic position. By virtue of the design, the valve has no ventricular protrusions and leaves no valve components in the annulus. In turn, this design allows for improved seating in a smaller annulus with the advantage of reducing the need for a root enlargement along with a potential 100% orifice to annulus match. The Top Hat is available for sizes ranging from 19 to 27 mm. The OptiForm valve has a symmetrical cuff design that allows the valve to be placed in a supra-annular, intra-annular or subannular position simply by varying suture entry and exit sites. This valve is available for the mitral position only and for sizes from 23 to 33 mm. The Reduced Series valve is an intra-annular valve and was designed primarily for a smaller annulus and root size. The small external diameter and the smaller, pliable cork-shaped sewing cuff allows for improved seating and once again provides the potential advantage of reducing the need for root enlargement. This valve is available for the aortic position only and for sizes from 19 to 29 mm. The Standard valve offers a generous sewing cuff and is available for the aortic and mitral position. Its low-profile pivot design reduces the risk of coronary obstruction for aortic valve replacements and limits protrusion into the atrium for mitral valve replacements, thus reducing potential thrombus formation. The valve is available in sizes from 19 to 31 mm in the aortic position and 21 to 33 mm in the mitral position. The Standard Pediatric valve was designed for small adults or pediatric patients and is available for both the aortic and mitral position. The placement of the aortic valve can be supra- or intra-annular, and the valve available in sizes from 16 to 18 mm. The mitral valve is available in 16 and 18 mm for either supra- or intra-annular placement, while a 21-mm valve is designed for intra-annular placement only. The Orbis valve, available only outside the United States, has a multipurpose cuff design that allows for a variety of implantation techniques. This valve is offered for both aortic and mitral valve replacement and will fit sizes from 19- to 31-mm in the aortic position and 21- to 33-mm in the mitral position. All CarboMedics valves are rotatable *in situ*.

A number of reports have been published demonstrating good clinical outcomes using the Bicarbon and CarboMedics Series.^{32,33} The specific types of Bicarbon or CarboMedics valves used, however, are not detailed in these reports. Azarnoush and colleagues³⁴ reported the 15-year clinical outcomes of the Sorin Bicarbon prosthesis from a multicenter European study where 1704 patients received aortic valve replacement, mitral valve replacement, or both. Actuarial freedom from valve-related deaths at 15 years was 76.4%, and actuarial freedom from thromboembolism, hemorrhage, and endocarditis at 15 years was 88.8%, 77.5%, and 96.8%, respectively. No cases of structural failure were observed.³⁴ Bouchard and colleagues³⁵ reported their 20-year experience with 3297 patients who received a CarboMedics

valve as an aortic valve replacement or mitral valve replacement. At 20 years, freedom from valve-related mortality for AVR and MVR was 78.3% and 74.6%, respectively. Freedom from thromboembolic events, reoperation, and bleeding were 91.6%, 89.2%, and 89.5% for AVR and 88.5%, 80.3%, and 88% for MVR, respectively. Freedom from endocarditis was 97.3% for both AVR and MVR.³⁵ In a direct comparison, Bryan and colleagues²⁴ reported the 10-year follow-up of their prospective randomized trial where 485 patients received either the CarboMedics valve or the SJM mechanical valve in either the aortic position, mitral position or both. Freedom at 10 years from valve-related mortality was 95.0% in the CarboMedics group and 93.0% in the SJM group. Linearized rates per patient-year were 1.1% in the CarboMedics group and 0.8% in the SJM group for thromboembolism; 2.3% in the CarboMedics group and 3.2% in the SJM group for bleeding events; and 0.72% in the CarboMedics group and 0.47% in the SJM group for nonstructural valve dysfunction.²⁴

On-X Life Technologies. The On-X Heart Valve (On-X Life Technologies, Austin, TX; see Fig. 75-1D) is a bileaflet valve constructed completely of pyrolytic carbon. The manufacturer claims that the lack of silicon doping in the valve's carbon construction potentially decreases its thrombogenicity. Its design includes a tall, flared inlet that increases the orifice area and decreases the ability of retained valve tissue to interfere with opening and closing. In addition, the stasis-free pivot design allows the valve to wash itself, and the 90-degree leaflet opening provides improved laminar flow and reduced turbulence. The On-X Heart Valve is available for both aortic and mitral valve replacement. There are three different sewing rings available, each catered to a particular clinical setting. The valve construct within the three sewing rings is the same. The Standard ring is available in sizes from 19 to 27/29 mm in the aortic position and 23 to 31/33 mm in the mitral position. The Conform X model provides a more flexible sewing ring and is available in sizes from 19 to 27/29 mm in the aortic position, whereas for the mitral position it offers one size that is intended to fit an annular size ranging from 25 to 33 mm. The Anatomic sewing ring is designed to fit the contours of the aortic valve annulus and is available in sizes ranging from 19 to 27/29 mm.

Under FDA investigational device exemption, the Prospective Randomized On-X Anticoagulation Clinical Trial (PROACT) has been testing the safety of less aggressive anticoagulation than recommended by the American College of Cardiology and American Heart Association guidelines after implantation of the On-X valve. In the first limb of the PROACT, Puskas and colleagues³⁶ reported their results of 375 patients with elevated risk factors for thromboembolism who underwent an aortic valve replacement. While receiving 81 mg of aspirin daily, patients received either low-dose warfarin with a target international normalized ratio (INR) of 1.5 to 2 or standard warfarin dosing targeting an INR of 2 to 3. The mean INR was 2.50 ± 0.63 for the control group and 1.89 ± 0.49 for the low dose group ($P < 0.0001$). The low-dose group experienced significantly lower

major (1.48% vs. 3.26% per patient-year; $P = 0.047$) and minor (1.32% vs. 3.41% per patient-year; $P = 0.021$) bleeding rates. The incidence of stroke, transient ischemic attack, total neurologic events, and all-cause mortality were similar between the two groups.³⁶ Enrollment for the low-risk aortic and mitral valve replacement arm of the PROACT was completed in 2013.

Bioprosthetic Valves

The inherent clinical benefit of bioprosthetic valves lies with the patient's ability to avoid life-long anticoagulation. Long-term durability, however, remains the Achilles heel of these valves. During the years since the first valve replacement with a porcine xenograft was reported by Binet and colleagues,³⁷ tissue fixation methods have concentrated on improving durability. First-generation bioprosthetic valves were treated with high-pressure (60 to 80 mm Hg) glutaraldehyde fixation; however, it soon became evident that this process led to calcification of the xenograft tissue.¹³ The pathophysiology of calcification is not well understood, but it is believed to be related partly to the affinity of calcium for aldehyde groups that are generated by glutaraldehyde along with the affinity of calcium for collagen in the extracellular matrix of the cells exposed to glutaraldehyde.³⁸ Damage caused by shear stress-induced turbulence is also a contributing factor leading to calcification.³⁹ Amino oleic acid treatment of tissue valves has been shown to prevent calcium from binding to collagen.⁴⁰ Low-pressure and zero-pressure glutaraldehyde fixations have been shown to maintain a more natural collagen alignment and are currently part of the strategies used for bioprosthetic valves. More recently, valve manufacturers have developed proprietary anticalcification strategies for bioprosthetic valves; however, the true efficacy of these treatments has yet to be determined.

Stented Porcine Bioprostheses

Medtronic. The Hancock II is a porcine bioprosthesis that has a record for safety and durability greater than 25 years. The valve is available in sizes ranging from 21 to 29 mm in the aortic position and 25 to 33 mm in the mitral position. The Hancock II Ultra features a reduced sewing cuff designed specifically for supra-annular implantation in a small aortic root, and it is available in sizes ranging from 21 to 29 mm. The valves are treated with sodium dodecyl sulfate (T6), which removes phospholipids in an effort to reduce calcification. A modified fixation process minimizes the septal muscle shelf, thus leading to a larger orifice area and subsequent better hemodynamics. The Cinch Implant System pulls the stent posts centrally and therefore serves as an automated deflection system to assist with suture tying; it further facilitates aortic valve insertion, particularly through a tight sinotubular space, and helps to prevent suture "looping" around stent posts for mitral valve replacement. Several reports have demonstrated good long-term outcomes with the Hancock II.^{41,42} Valfre and colleagues⁴³ reported their experience of 517 patients who received the valve in the aortic or mitral positions. Late freedom

from reoperation was 85.5% and 79.3% at 15 and 20 years, respectively, in the AVR population, whereas in the MVR population it was 73.3% and 52.8%, respectively.⁴³

The Mosaic valve (Fig. 76-2A) is the next generation of porcine bioprosthesis developed by Medtronic. The valve undergoes zero-pressure glutaraldehyde fixation to maintain collagen crimp morphology and leaflet flexibility. The valve also undergoes anticalcification treatment with alpha-amino oleic acid in an effort to reduce leaflet calcification. It has a low-profile semiflexible stent, and its porcine root is predilated in an attempt to maximize valve orifice area. The valve is available in sizes ranging from 19 to 29 mm in the aortic position and 25 to 33 mm in the mitral position. The Mosaic Ultra has a reduced scalloped sewing cuff that conforms to the aortic annulus for complete supra-annular placement and is available in sizes from 19 to 29 mm. The Cinch Implant System is also available for the Mosaic and Mosaic Ultra. Once again multiple groups have reported good durability and safety using this valve.⁴⁴⁻⁴⁷ Twelve-year data on 1029 patients receiving either an AVR or MVR was reported by Jamieson and colleagues.⁴⁶ Freedoms from valve-related mortality were $87.1\% \pm 3.1\%$ for AVR and $82.5\% \pm 7.7\%$ for MVR, whereas freedoms from reoperation were $84.0\% \pm 3.3\%$ for AVR and $82.5\% \pm 7.5\%$ for MVR. Lastly, freedoms from structural valve deterioration by explant reoperation at 12 years for AVR were $93.3\% \pm 2.6\%$ for patients at least 60 years old and $75.9\% \pm 9.3\%$ for patients younger than 60 years. The 15-year compendium of the same cohort published by Medtronic demonstrates continued durability and good clinical outcomes.

Edwards Lifesciences. The Carpentier-Edwards standard porcine valve (see Fig. 76-2B) is a stented bioprosthesis that was introduced in 1975. The leaflets are fixed with glutaraldehyde at moderate pressure (60 mm Hg) and mounted on a flexible cobalt-chromium alloy stent. The septal muscle shelf is sewn onto the stent to prevent obstruction of the valve inlet orifice. In addition, the leaflets receive the proprietary XenoLogiX treatment, which is designed to reduce calcification by extracting up to 95% of leaflet membrane phospholipids. The valve is available for both the aortic (model 2625) and mitral (model 6625) positions, in sizes ranging from 19 to 31 mm and 25 to 33 mm, respectively. The Carpentier-Edwards S.A.V. valve (CE-SAV; model 2650) is the next-generation porcine bioprosthesis that was introduced in 1982 to improve valve durability and transvalvular gradients observed with the Standard design. The valve is constructed using the same flexible cobalt-chromium alloy stent and XenoLogiX-treated leaflets. The glutaraldehyde fixation process, however, was reduced from moderate to low pressure (2 mm Hg). It features a low-profile design to prevent coronary obstruction in the aortic position and to decrease protrusion into the left ventricular outflow tract in the mitral position. The aortic prosthesis is designed for supra-annular placement to improve transvalvular gradients and EOA, and it has a scalloped contour for better anatomic fit. The aortic valve is available in sizes ranging from 19 to 31 mm; however, the 19, 29, and 31 mm sizes are available only outside the United States. The mitral prosthesis (model 6650) is available in sizes ranging from 25 to 33 mm and is available only outside the United States.

FIGURE 76-2 ■ Stented porcine valves. **A**, Mosaic Bioprosthesis. **B**, The Carpentier-Edwards Standard porcine valve. **C**, The Epic porcine valve. (**A**, Courtesy Medtronic, Inc., Minneapolis, MN. **B**, Courtesy Edwards Lifesciences Corp., Irvine, CA. **C**, Courtesy St. Jude Medical, Inc., Minneapolis, MN.)

The Carpentier-Edwards Duraflex low-pressure mitral porcine valve (model 6625LP) has all the same structural and design features as the CE-SAV mitral valve, and it is available only in the United States. The extended sewing ring model (model 6625-ESR-LP) is designed to offer greater ease of implantation when a larger suture surface is required. This valve is available in sizes ranging from 27 to 35 mm.

Jamieson and colleagues⁴⁸ reported their 20-year experience with the CE-SAV, which included 1823 patients who underwent AVR. Overall actual freedom from reoperation at 18 years was $85.0\% \pm 1.2\%$. Furthermore, the actual freedom from structural valve deterioration at 18 years was $86.4\% \pm 1.2\%$ overall; $90.5\% \pm 1.8\%$ for age 61 to 70 years; and $98.2\% \pm 0.6\%$ for age greater than 70 years.⁴⁸ The only long-term study that evaluated the performance of the porcine mitral valve was by Corbineau and colleagues,⁴⁹ using the Standard valve. Of 139 patients who received the prosthesis, 30 demonstrated structural valve deterioration, with a mean time to onset of 9.0 ± 2.7 years. Although structural valve deterioration was independent of age, the frequency of deterioration was higher in younger recipients. After the age of 65 years, the frequency of structural valve deterioration was no longer variable.⁴⁹

St. Jude Medical. The Biocor valve is a stented porcine bioprosthesis with 20 years of established clinical experience.^{50,51} The valve was acquired by SJM in 1996 and approved by the FDA in 2005. It is available for the aortic and mitral positions in sizes ranging from 21 to 29 mm and 25 to 33 mm, respectively. The design features a flexible stent that adapts easily to the annulus and provides greater ease for knot tying. In addition, its low profile minimizes aortic wall protrusion and reduces left ventricular outflow tract obstruction in the mitral position. The Biocor Supra is designed for supra-annular implantation in the aortic position with the intention of providing better hemodynamics, and it is available in sizes ranging from 19 to 27 mm. The Epic (see Fig. 76-2C) and Epic Supra series use the same valve design as Biocor with the added benefit of receiving the Linx AC Technology, a patented, proprietary anticalcification treatment, designed to improve long-term performance and valve durability. The Epic series was approved by the FDA in 2007, and it is available for the same valve positions and sizes as the Biocor series.

Mykén and colleagues reported their 20-year data of 1712 patients who received the Biocor valve in either the aortic or mitral position. Actuarial freedom from reoperation because of structural valve deterioration was $61.1\% \pm 8.5\%$ and $79.3\% \pm 6.0\%$ after aortic valve replacement and mitral valve replacement, respectively.⁵¹ The results of the FDA regulatory investigation of Epic valve were reported by Jamieson and colleagues,⁵² in which 761 patients received the Epic valve in the aortic position, the mitral position, or both. The actuarial freedom from reoperation at 4 years, because of structural valve deterioration for AVR for age 60 years or less, was $93.3\% \pm 6.4\%$; for ages 61 to 70 years, $98.1\% \pm 1.9\%$; and for older than 70 years, 100% ($P = 0.0006$ for >70 vs. ≤ 60 years). There were no events of structural

deterioration with mitral valve replacement. The actuarial freedom from major thromboembolism for all patients at 4 years was $93.6\% \pm 1.0\%$.⁵²

Stented Bovine Pericardial Bioprostheses

Edwards Lifesciences. The Carpentier-Edwards PERIMOUNT valves are stented bovine pericardial bioprostheses with up to 25 years of demonstrated clinical durability. All PERIMOUNT valves feature a flexible cobalt-chromium alloy stent designed to absorb energy during the cardiac cycle, with three independent symmetrical pericardial leaflets mounted beneath the stent. The leaflets undergo a proprietary stress-free fixation, and they are meticulously matched for thickness and elasticity. The aortic heart valve series consists of the 2700 model, which undergoes XenoLogiX anticalcification treatment, and the 2700TFX model, which undergoes the ThermoFix process, a next generation anticalcification treatment that cross-links unstable glutaraldehyde moieties, in addition to reducing membrane phospholipids. The reduced sewing ring aortic heart valve series consists of the 2800 model and the 2800TFX model. Models 2900 and 2900TFX, available only outside the United States, are identical to models 2800 and 2800TFX, respectively. This series features a reduction in the sewing ring size by 2 to 3 mm, depending on the valve size, and it is designed to facilitate implantation into a smaller aortic root. The two models are distinguished by their anticalcification treatments, with the 2800 receiving the XenoLogiX treatment and the 2800TFX undergoing the ThermoFix process. The Magna aortic heart valve series (3000 and 3000TFX models) further improved the valve design by positioning the stent on top of the sewing ring rather than occupying space within the ring, effectively increasing the EOA and therefore improving valve hemodynamics. Once again, the two models differ only in their anticalcification strategies. Lastly, the Magna Ease aortic heart valve series (3300TFX model) features the same stent placement above the sewing ring, but with a lowered stent base that reduces the overall profile of the valve (Fig. 76-3A). The lower profile maximizes coronary ostia clearance and ease of aortotomy closure. This is the only valve series that is exclusively treated with the ThermoFix anticalcification process. All aortic models are available in sizes ranging from 19 to 29 mm.

A number of reports have documented the long-term safety and durability of the PERIMOUNT valve in the aortic position.^{53,54} Vakil and colleagues⁵⁵ reported the rate of structural valve deterioration, as well as the risk factors influencing this phenomenon for 12,569 patients over a 20-year period. Actuarial rates of explantation for SVD at 10 and 20 years were 2% and 15%, respectively. Younger age ($P < 0.0001$) and higher total cholesterol ($P = 0.002$) were associated with increased risk of explantation for SVD. Smaller valve sizes alone were not associated with increased risk for valvular deterioration; however, higher postoperative peak and mean gradients were significant predictors of SVD ($P < 0.0001$).⁵⁵

The mitral heart valve series features the same design and structural elements as the aortic series. The 6900P model (PERIMOUNT Plus mitral heart valve) and the

FIGURE 76-3 ■ Stented bovine pericardial valves. **A**, The Carpentier-Edwards PERIMOUNT valve. **B**, The Mitroflow valve. **C**, The Tri-fecta valve. (**A**, Courtesy Edwards Lifesciences Corp., Irvine, CA. **B**, Courtesy Sorin Group, Inc., Milan, Italy. **C**, Courtesy St. Jude Medical, Inc., Minneapolis, MN.)

6900PTFX model differ only in the anticalcification strategies they receive. The Magna Mitral Ease valve (7300TFX) design modifications feature an asymmetric and widened sewing cuff designed to increase the effective suture area and to enhance coaptation between the anterior and posterior aspects of the native mitral annulus. The low-profile design limits projection into the left ventricular outflow tract, and the anatomic sewing ring is designed to tilt the valve away from the left ventricular free wall to reduce the risk of left ventricular free wall abrasion. The Magna Mitral Ease valve exclusively receives the ThermoFix anticalcification treatment. The entire mitral PERIMOUNT valve portfolio includes the Tricentrix holder system, which is intended to prevent inadvertent looping of valve sutures around the stent posts during surgical implantation. All PERIMOUNT mitral valve prostheses are available in sizes ranging from 25 to 33 mm.

Bourguignon and colleagues reported their 20-year outcomes of the PERIMOUNT valve placed in the mitral position in 404 patients. Actuarial freedom from explant because of structural valve deterioration at 20 years was $40.5\% \pm 8.0\%$ (1.9% per valve-year). Competing risk analysis demonstrated an actual risk of explant caused by structural valve dysfunction at 20 years of $25.5\% \pm 2.9\%$. Rates of valve failure were inversely correlated with recipient age, and the expected valve durability was 16.6 years for the entire cohort (11.4, 16.6, and 19.4 years for the patients younger than 60 years, between 60 and 70 years, and older than 70 years, respectively). Actuarial freedom from thromboembolism was $83.9\% \pm 7.6\%$ (0.5% per valve-year), freedom from hemorrhage

was $80.2\% \pm 10.8\%$ (0.7% per valve-year), freedom from endocarditis was $94.8\% \pm 1.4\%$ (0.4% per valve-year), and freedom from structural valve dysfunction was $23.7\% \pm 6.9\%$ (2.3% per valve-year).⁵⁶

Sorin Group. The Mitroflow valve (see Fig. 76-3B) is a stented bovine pericardial bioprosthesis designed for supra-annular implantation in the aortic position. The valve has been available worldwide, except in the United States, since 1982. The current model was introduced in 1991 and was approved by the FDA in 2007.⁵⁷ The valve design features a single pericardial sheet that is mounted around the stent posts, giving it a cylindrical wide leaflet opening for improved hemodynamics. The valve is constructed on a flexible polymer stent that couples maximal flow area with structural strength and resistance to permanent deformation. Its small sewing ring and low profile are designed to ease implantation. The leaflets undergo phospholipid reduction treatment (PRT), a proprietary anticalcification strategy recently approved in the United States. The valve is available in sizes from 19 to 29 mm.

The ISTHMUS investigators reported their results of a multicenter experience with Mitroflow over a 20-year period in which 1591 patients underwent an AVR. Reoperation was required in 96 patients (5.9%), of whom 59 patients (3.7%) had repeated surgery for structural valve degeneration. The actuarial freedom from prosthetic valve degeneration at 18 years was 65.5% (78% in patients older than 70 years) with a linearized rate of 1.4 patients per year (0.8 patients per year in patients older than 70 years). At 18 years, freedom from embolism was 82% (0.9 patients per year), freedom from valve

endocarditis was 89% (0.6 patients per year) and freedom from bleeding episodes was 95% (0.2 patients per year), respectively.⁵⁸

The Soprano Armonia valve is a stented bovine pericardial bioprosthesis designed for supra-annular implantation in the aortic position. It features a soft and easy-fitting sewing ring treated with Carbofilm coating for enhanced hemo-biocompatibility along with a low profile and scalloped stent. The leaflets have a double-sheet design intended to avoid contact between the pericardium and synthetic material. The tissue undergoes postfixation detoxification with homocysteic acid, which neutralizes residues of unbound aldehyde groups, aimed at improving performance in terms of durability, safety, and biocompatibility. The valve is available in sizes ranging from 19 to 33 mm and is clinically approved for use outside the United States only. Fischlein and colleagues⁵⁹ reported the European multicenter study using the Soprano valve in 501 patients at 1 year. Freedom from valve-related death was 98.6%, and actuarial freedoms from thromboembolism, bleeding, endocarditis, and paravalvular leak were 97.1%, 98.9%, 99.1%, and 99.6%, respectively. No events of thrombosis and SVD were observed. They also demonstrated a significant reduction in left ventricular mass, from 211 ± 78.5 g at 1 month to 185 ± 64.7 g at 12 months ($P < 0.0001$).⁵⁹

The Pericarbon More valve is a stented bovine pericardial bioprosthesis designed for placement in the mitral position only. In addition to all the design features and treatments of the Soprano, it has the addition of an anti-looping protection system. The valve is available in sizes ranging from 19 to 33 mm and is clinically approved for use outside the United States only. The largest series using the valve in the mitral position was reported by Caimmi and colleagues.⁶⁰ At a single institution, 78 patients underwent an MVR by the same surgeon using the 29-mm valve. At 12 years, valve-related survival rate was $93.1\% \pm 3.0\%$ while freedom from embolic events was $83.0\% \pm 4.5\%$ and freedom from endocarditis was $98.7\% \pm 1.3\%$. The freedom from primary tissue failure was $56.8\% \pm 6.6\%$ with an $86.3\% \pm 7.5\%$ rate in patients older than 60 years and a $36.8\% \pm 8.2\%$ rate in younger patients.⁶⁰

St. Jude Medical. The Trifecta valve (see Fig. 76-3C) is a stented bovine pericardial bioprosthesis designed for supra-annular implantation in the aortic position that was approved by the FDA in 2011. The valve stent is made from fatigue-resistant, high-strength titanium, designed to reduce stress on the leaflets during the cardiac cycle. The stent posts are covered by porcine pericardium to provide tissue-to-tissue contact between the valve leaflets and stent to reduce leaflet abrasion and potential valve deterioration. The leaflets are from a single sheet of bovine pericardium that is externally mounted to optimize coaptation and maximize flow. Proper leaflet shaping and coaptation are achieved through a proprietary tissue leaflet fixation process. Lastly, the leaflets are treated with the Linx AC Technology aimed toward anticalcification. The valve is available in sizes ranging from 19 to 29 mm.

Results from the global, multicenter, prospective clinical study for Trifecta, in which 1014 patients received

implants at 31 centers, were reported by Bavaria and colleagues.⁶¹ Overall freedom from valve explant was 99.4% at 2 years. At the time of discharge, average mean gradients ranged from 9.3 to 4.1 mm Hg for valve sizes ranging 19 to 29 mm, respectively. There were 27 early thromboembolic events, including 8 (0.8%) strokes, 17 (1.7%) reversible neurologic events, and 2 (0.2%) systemic embolic events. There were no instances of early valve thrombosis, endocarditis, or clinically significant hemolysis. Lastly, there were five late valve explants, including one for structural deterioration and four for endocarditis.⁶¹

Stentless Bioprostheses

The first use of a xenograft stentless valve for aortic valve replacement was in 1986.¹⁵ Because these prostheses have no rigid metal stent, there is little or no inherent gradient across the valve. These valves are supported by the aortic root of the patient once they are implanted by the sub-coronary or inclusion cylinder technique. Certain stentless valves can also be implanted as stand-alone aortic root replacement prosthesis, similar to that of a homograft. Implantation of these valves, however, is more complex and often associated with longer cross-clamp times. These issues, along with the evolution of stented bioprostheses toward decreasing transvalvular gradients, have reduced the popularity of stentless valves in recent years.

Medtronic. The Freestyle valve (Fig. 76-4A) is a stentless porcine bioprosthesis with up to 15 years of demonstrated clinical durability. The valve is a full porcine root that undergoes a proprietary physiologic fixation process that is designed to retain the valve's natural anatomical shape along with alpha-amino oleic acid anticalcification treatment. It can be used as a freestanding aortic root prosthesis, or it can be trimmed and implanted with a subcoronary technique. The valve is available in sizes ranging from 19 to 29 mm. Bach and colleagues⁶² reported their long-term outcomes of a multicenter cohort from North America and Europe where 725 patients were followed for up to 15 years. Freedom from valve-related death at 10 and 15 years was $94.9\% \pm 1.5\%$ and $92.7\% \pm 3.5\%$. Freedom from explant owing to structural valve deterioration was $96.5\% \pm 1.3\%$ and $83.3\% \pm 4.8\%$ at 10 and 15 years, respectively. Increased age was associated with a lower risk of reoperation and explant caused by structural valve deterioration.⁶²

The 3f (form follows function) valve is a stentless bioprosthesis made from three equal equine pericardial leaflets that undergo zero pressure fixation. Its tubular design was aimed to mimic the physiological function of the native aortic valve as closely as possible. The valve is affixed both to the annulus and with sutures at the commissural posts, creating greater valve flexibility and thus facilitating implantation. Given its unique design, the point of maximal stress on the valve is shifted from the commissure to the semilunar "belly" of leaflet. The valve is available in sizes ranging from 19 to 29 mm. Linneweber and colleagues⁶³ reported a 5-year follow-up of 123 patients receiving the 3f valve. There was no severe

FIGURE 76-4 ■ Stentless valves. **A**, Freestyle Aortic Root Bioprosthesis. **B**, The Freedom Solo valve. **C**, The Prima Plus valve. (**A**, Courtesy Medtronic, Inc., Minneapolis, MN. **B**, Courtesy Sorin Group, Inc., Milan, Italy. **C**, Courtesy Edwards Lifesciences Corp., Irvine, CA.)

structural or nonstructural valve dysfunction identified. Freedom from endocarditis was 100%, and there was minimal paravalvular regurgitation detected in four patients. Collectively, this resulted in a 100% freedom from reoperation. Freedom from severe adverse events was 89%, which included one permanent and three transient neuroembolic events. The mean transvalvular gradients remained low, and the ventricular mass was significantly improved.⁶³

Sorin Group. The Pericarbon Freedom is a stentless bovine pericardial bioprosthesis that undergoes the manufacturer's postfixation detoxification treatment; it is stored in an aldehyde-free solution, thus eliminating the need for rinsing before implantation. It can be used as a freestanding aortic root prosthesis, or it can be trimmed and implanted with a subcoronary technique. The valve is available in sizes ranging from 15 to 29 mm, and is clinically approved for use outside the United States only. Milano and colleagues⁶⁴ reported 10-year outcomes for 85 patients who received the Pericarbon Freedom valve. Actuarial freedom from structural valve deterioration was $96\% \pm 3\%$. Two patients required reoperation because of SVD, one for endocarditis and one for dilation of the sinotubular junction, resulting in an actuarial freedom from reoperation of $93\% \pm 4\%$. Left ventricular mass index decreased from 213 ± 51 gm/m² to 157 ± 43 gm/m² ($P < 0.001$).⁶⁴

The Freedom Solo (see Fig. 76-4B) is a next-generation stentless bovine pericardial bioprosthesis, designed for supra-annular seating aimed at establishing a 100% orifice-to-annulus ratio. The valve is designed for subcoronary implantation only and is available in sizes ranging from 19 to 27 mm. It is currently available only outside the United States, but it is expected to receive FDA approval in the near future. A number of reports have demonstrated low transvalvular gradients after implantation and associated regression of left ventricular mass within several months; however, long-term data on the durability of the valve are not available.^{65,66} There have also been several reports of severe but transient thrombocytopenia in patients that receive the valve,

relative to other available options.^{67,68} The etiology of the thrombocytopenia is unknown.

Edwards Lifesciences. The Edwards Prima Plus valve (see Fig. 76-4C) is a stentless porcine bioprosthesis that undergoes low-pressure fixation and receives XenoLogiX anticalcification treatment. A woven polyester cloth is sewn to the annulus to provide additional support to the first suture line. It can be implanted as a full root replacement or trimmed and placed using a subcoronary technique; however, the approved indication in the United States is for the subcoronary implantation only. The valve is available in sizes ranging from 21 to 29 mm. Auricemma and colleagues⁶⁹ reported their 10-year outcomes in 318 patients who received the Edwards Prima Plus valve. Actuarial freedom from valve reoperation and structural valve deterioration at 10 years were 100% and 64%, respectively. Actuarial freedom from embolic events and endocarditis at 10 years were 84% and 81%, respectively.⁶⁹

Sutureless Valves

Sutureless prosthetic heart valves were initially developed in the 1960s to facilitate valve implantation while reducing ischemic and procedural times. These valves were abandoned, however, because of multiple complications such as paravalvular leaks and valve-related thromboembolic events.⁷⁰ The rapid development of transcatheter technology has fueled a reemergence of the sutureless strategy, once again in an effort to reduce the morbidity and mortality of patients requiring valve replacement. The acceleration of the surgical procedure has the potential to reduce the adverse outcomes seen in higher-risk patients and in those requiring complex multivalve or combined valve and coronary procedures.⁷¹

Medtronic. The 3f Enable (Fig. 76-5A) is a sutureless bioprosthesis constructed with the 3f stentless valve placed over a self-expanding nitinol frame. The inflow flange is covered with polyester fabric and is scalloped to conform to the aortic annulus. Implantation requires a

FIGURE 76-5 ■ Sutureless valves. A, The 3f Enable valve. B, The Perceval S valve. C, The Intuity valve. (A, Courtesy Medtronic, Inc., Minneapolis, MN. B, Courtesy Sorin Group, Inc., Milan, Italy. C, Courtesy Edwards Lifesciences Corp., Irvine, CA.)

transverse aortotomy at least 2 cm above the sinotubular junction. As with traditional sutured valves, the leaflets must be excised followed by meticulous débridement of the annulus. A single guiding suture is placed in the nadir of the noncoronary sinus, and the valve commissures need to be aligned to the native valve commissures. The chronic outward force of the nitinol, along with the polyester flange, ensure fixation of the valve and minimize the potential for paravalvular leaks.⁷¹ The valve is contraindicated in bicuspid aortic valves along with irregular or heavily calcified valves. It received CE Mark approval in 2009 and is currently awaiting FDA approval. The valve is available in sizes ranging from 19 to 29 mm. A number of groups have reported their outcomes with the 3f Enable.^{72,73} Eichstaedt and colleagues⁷³ reported their single-center experience of 120 patients with up to 18 months of follow-up. In a population of patients with a mean Society of Thoracic Surgeons risk score of 14.8%, the 30-day mortality was 6.7% overall and 1.4% in stand-alone procedures. Mean and peak transvalvular gradients were 9 mm Hg (4 to 13 mm Hg) and 14 mm Hg (8 to 22 mmHg) at discharge, respectively. In 8 patients (6.7%), permanent pacemaker implantation was necessary. No thromboembolic or bleeding events related to the bioprosthesis were observed.⁷³

Sorin Group. The Perceval S (see Fig. 76-5B) is a stentless, bovine pericardial bioprosthesis attached to a self-expandable nitinol anchoring device, which has the dual role of supporting the valve and providing fixation to the implantation site. The anchoring device is characterized by two ring segments (outflow and inflow ring), three commissural elements supporting the valve, and three pairs of sinusoidal elements providing fixation in the sinuses of Valsalva. The anchoring device is treated with the manufacturer's proprietary Carbofilm coating. In addition to the double-sheet pericardial design, there is a pericardial sealing collar designed to encourage adaptation to the aortic annulus and prevention of paravalvular leaks. The proximal aortotomy should be 3 to 3.5 cm above the valve annulus or 0.5 to 1 cm above the sinotubular junction. The leaflets must be excised; however, the annulus does not require decalcification. Only eccentric

and bulky intra-annular calcium needs to be removed. Guiding sutures are then placed 2 to 3 mm below the nadir of each sinus, maintaining 120 degrees equidistance between each suture. In correspondence to each valve sinus, a buttonhole is provided on the inflow ring, through which the guiding sutures are passed. Before implantation, the prosthesis diameter is reduced to a suitable size and then loaded on the holder. After in situ positioning, the valve is released in two steps. First the inflow ring at the level of the annulus and, when proper positioning is verified, the complete prosthesis is released. Following implantation, a postdilation balloon catheter is inflated inside the prosthesis at the inflow level to improve apposition by modeling the inflow ring on the annulus.⁷¹ The valve is available in small (S), medium (M), large (L), and extra-large (XL) sizes. The valve received CE Mark approval in 2011, and it is expected to receive FDA approval shortly.

Several reports have demonstrated the safety and efficacy of the valve.^{74,75} Rubino and colleagues⁷⁶ reported a multicenter European cohort of 314 patients who underwent AVR using the Perceval S as a standalone procedure or combined with surgical revascularization. The valve was successfully implanted in 99.4% of cases, whereas two patients were converted to a traditional AVR because of severe paravalvular leak. In-hospital mortality was 3.2% and was lower in isolated AVR compared with a combined procedure (1.4% vs. 7.4%; $P = 0.005$). Six patients (1.9%) experienced perioperative stroke, five (1.6%) needed renal replacement therapy, and 25 (8.0%) required pacemaker implantation. Octogenarians and younger patients experienced similar in-hospital outcomes. At 2 years, overall survival was $84.1\% \pm 4.2\%$, whereas freedom from valve-related death was $97.9\% \pm 1.3\%$. Freedom from stroke was $98.9\% \pm 0.8\%$, freedom from endocarditis was $99.1\% \pm 0.6\%$, and freedom from reoperation on the aortic valve was $98.5\% \pm 0.9\%$. Once again, no differences were observed in octogenarians compared with the younger population.⁷⁶

Edwards Lifesciences. The Edwards Intuity (see Fig. 76-5C) is a stentless bovine pericardial bioprosthesis that uses the PERIMOUNT design with a proprietary

balloon-expandable subannular stainless steel frame. The leaflets receive the manufacturer's ThermoFix anticalcification treatment, and the frame is covered with a broad polyester sealing cloth that is expanded slightly below the native aortic valve annulus. Implantation is performed after a traditional aortotomy and excision of the leaflets. Decalcification of the annulus should be performed to where the inner surface of the annulus is smooth. Guiding sutures are placed through the annulus at the nadirs of each sinus and are later secured to the valve. The Intuity received CE Mark approval in 2012, and it is currently being trialed in the United States for future FDA approval. The valve is available in sizes ranging from 19 to 27 mm. The Surgical Treatment of Aortic Stenosis With a Next Generation Surgical Aortic Valve (TRITON) trial reported the 1-year outcomes of 152 patients who underwent AVR using the Edwards Intuity valve. Implantation was successful in 96.1% of patients (146/152), whereas early valve-related mortality was 1.4% and cumulative survival was 92.5% at a mean follow-up of 9.8 ± 5.1 months. Independent core laboratory-adjudicated mean effective orifice area and aortic valve pressure gradient were 1.7 ± 0.2 cm² and 8.8 ± 3.0 mm Hg at 3 months, and 1.7 ± 0.2 cm² and 8.4 ± 3.4 mm Hg at 1 year, respectively.⁷⁷

Transcatheter Valves

Transcatheter valves have created a paradigm shift in the approach to treating valvular heart disease. With the approval of the Edwards Sapien aortic valve and the Medtronic CoreValve, a new generation of valvular therapy was introduced. Approved for nonoperative and high-risk surgical patients with aortic stenosis, these valves have demonstrated significant benefits over medical therapy and comparable outcomes to traditional surgical aortic valve replacement.⁷⁸⁻⁸⁰ SJM has received CE Mark approval for the Portico aortic valve, which is being trialed in the United States for future FDA approval. Transcatheter approaches to mitral, tricuspid, and pulmonary valve replacements are being developed as well, and will likely be clinically available in the near future. As this technology evolves, it will likely reshape the indications for surgical valve replacement while further improving the care of patients with valvular heart disease. A more detailed review of transcatheter valve therapies is presented in [Chapter 79](#).

Homograft Valve Replacement

Homograft valves are harvested from cadaveric donors and cryopreserved until they are ready for use. They are commonly used in congenital cardiac surgery for reconstruction of complex great vessel and semilunar valve anomalies. Currently, the primary indication for a homograft in adult cardiac surgery is as a full root replacement for complicated native aortic valve endocarditis⁸¹ or infected composite aortic root grafts. Initially there was optimism that homograft valves would offer improved durability over conventional bioprosthesis; however, studies have shown that modern biologic valves are equal if not greater in durability.⁸² Subcoronary and inclusion

techniques for implantation were initially described, but these approaches have fallen out of favor. For effective treatment of endocarditis, all infected tissue has to be radically debrided. To that end, the mitral valve curtain and attached septal muscle of the homograft can help in reconstructing the mitral annulus and left ventricular outflow tract. The absence of prosthetic material can offer an advantage that allows complex reconstructions in the presence of an infected field.

CHOICE OF VALVE REPLACEMENT

The choice of valve prosthesis can be a challenging decision faced by both the surgeon and patient. The first and most important step in the process is choosing between a mechanical and bioprosthetic valve. Important factors to consider are the patient's age, life expectancy, preference, indications or contraindications to anticoagulation, and comorbidities. The 2006 American College of Cardiology/American Heart Association (ACC/AHA) and 2007 European guidelines reduced the weight placed on the patient's age and gave greater emphasis to patient preference.^{83,84} The most recent ACC/AHA guidelines further emphasize that the choice of prosthetic valve type should be a shared decision-making process that accounts for the patient's values and preferences, with full disclosure of the indications for and risks of anticoagulant therapy and the potential need for reoperation. A bioprosthetic valve is believed to be reasonable in patients older than 70 years and recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired. Either a bioprosthetic or mechanical valve is considered reasonable in patients between 60 and 70 years old, and a mechanical prosthesis is reasonable for AVR or MVR in patients younger than 60 years who do not have a contraindication to anticoagulation ([Table 76-3](#)).⁸⁵

Another important factor in the selection process is choosing a valve that provides optimal hemodynamic performance. The performance of the valve is determined by the size of the prosthesis that can fit the patient's annulus and by the total cross-sectional area of that prosthesis, or the EOA of the valve, that is available for blood flow. PPM occurs when the EOA of the implanted valve is too small relative to the patient's body surface area. The most widely accepted measure of PPM is the iEOA. In the aortic position, an iEOA greater than 0.85 cm²/m² is considered acceptable. Moderate PPM occurs when the iEOA is between 0.85 and 0.65 cm²/m², whereas severe PPM occurs when the iEOA is less than 0.65 cm²/m². Several reports have demonstrated that PPM after AVR is associated with less improvement in symptoms and functional class, impaired exercise tolerance, less regression of left ventricular hypertrophy, less improvement in coronary flow reserve, more adverse cardiac events, and increased short- and long-term mortality. Moreover, the effect of PPM is more pronounced in younger patients and in those with depressed left ventricular function.⁸⁶

It is important to understand that there are significant discrepancies between the actual dimensions of a valve prosthesis and the labeled prosthesis size when

TABLE 76-3 Summary of Recommendations for Prosthetic Valve Choice from 2014 AHA/ACC Guidelines

Recommendations	COR	LOE
Choice of valve intervention and prosthetic valve type should be a shared decision process.	I	C
A bioprosthesis is recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired.	I	C
A mechanical prosthesis is reasonable for AVR or MVR in patients younger than 60 years who do not have a contraindication to anticoagulation.	IIa	B
A bioprosthesis is reasonable in patients older than 70 years.	IIa	B
Either a bioprosthetic or mechanical valve is reasonable in patients between 60 and 70 years old.	IIa	B
Replacement of the aortic valve by a pulmonary autograft (the Ross procedure), when performed by an experienced surgeon, may be considered in young patients when VKA anticoagulation is contraindicated or undesirable.	IIb	C

AVR, Aortic valve replacement; COR, class of recommendation; LOE, level of evidence; MVR, mitral valve replacement; VKA, vitamin K antagonist.

comparing different models. Therefore, one must be cautious when evaluating the hemodynamic performance of different prosthesis models on the basis of the labeled size. A particular annulus can accommodate a size 21 valve from one manufacturer, whereas the same annulus can accommodate only a size 19 valve from an alternate manufacturer. In general, newer-generation valves have superior performance over older devices, and mechanical prostheses are better when compared with stented bioprostheses. A recent meta-analysis showed that stentless valves provide larger EOAs, reduced transprosthetic gradients, and greater left ventricular mass regression when compared with stented bioprostheses, but at the expense of prolonged cardiopulmonary bypass times. In the end, the choice of valve prosthesis is a multifactorial decision that should be individualized to the needs of each patient, with the intention of achieving an optimal hemodynamic and clinical outcome.⁸⁶

FUNCTIONAL ANATOMY OF THE AORTIC VALVE

The aortic valve is the last of four cardiac valves through which the blood is pumped before it goes to the rest of the body. It separates the left ventricular outflow tract from the aorta. Its main function is to prevent backward blood flow from the aorta to the left ventricle, while allowing the blood to flow forward during systole with minimal resistance. The normal aortic valve has three semilunar cusps (tricuspid): the left coronary, the right coronary, and the noncoronary cusps. Each cusp is attached below one of the three sinuses of Valsalva, which are slight dilations of the aorta associated with each cusp. These sinuses end at the sinotubular junction, which is the narrowest part of the aortic root. The fibrous skeleton supports the aortic valve and is continuous with the anterior leaflet of the mitral valve.

AORTIC STENOSIS

Epidemiology and Etiology

Isolated aortic stenosis (AS) is more common in men than in women and is found in 2% of people 65 years of age and older. The most common causes of AS include age-related calcific degeneration, bicuspid aortic valve, and rheumatic aortic valve. The distribution of these causes varies across age groups and geographic regions. Age-related degeneration is the most common cause of AS in patients older than 70 years. In contrast, bicuspid aortic valve calcification accounts for most surgical cases in patients younger than 70 years.

Pathophysiology

No appreciable gradient exists across the normal aortic valve during systole. In AS, gradual obstruction of the left

ventricular outflow leads to an increased left ventricular afterload and left ventricular wall stress, elevated left ventricular systolic and diastolic pressures, decreased aortic pressure, and prolonged left ventricular ejection time. Over time, this results in compensatory concentric left ventricular hypertrophy (LVH) to maintain ejection fraction. In patients with chronic severe AS, this compensatory mechanism may become insufficient, leading to gradual dilation and thinning of the left ventricle, and result in a decrease in ejection fraction and in congestive heart failure.

Myocardial oxygen supply and demand is also altered in AS. LVH, increased systolic pressure, and prolonged ejection time result in increased myocardial oxygen demand. Increased diastolic pressure and prolonged systolic ejection time result in decreased diastolic and myocardial perfusion time and hence myocardial oxygen supply. The alteration in myocardial oxygen supply and demand is the underlying mechanism behind myocardial ischemia in patients with AS, even in the absence of coronary artery disease.

Clinical Features

The classic symptoms of AS are angina, exertional syncope, and symptoms of congestive heart failure such as shortness of breath. The mechanisms for angina and congestive heart failure are explained in the previous section. The mechanism for syncope is likely related to the blunting of exercise-induced augmentation in stroke volume as a result of outflow obstruction coupled with exercise-induced peripheral vasodilation. These changes cause a drop in systemic blood pressure leading to cerebral hypoperfusion and syncope.

The classic physical finding is a crescendo-decrescendo systolic ejection murmur heard best at the second right intercostal space, which may variably radiate to the carotid arteries. A palpable thrill may be present in severe cases of AS. Palpation of the arterial pulse may reveal a weak and delayed pulse known as *pulsus parvus et tardus*.

Diagnosis and Grading

Two-dimensional transthoracic echocardiography is the most common modality for the diagnosis and grading of AS (Table 77-1). In most patients, this modality can reliably establish aortic jet velocity, aortic valve peak and mean gradients, and aortic valve area.

Natural History

Without intervention, symptomatic AS has dismal outcomes. Multiple studies consistently reported survivals of 3 years for angina and syncope and 1.5 to 2 years for dyspnea and heart failure.² These findings have driven recommendations for early surgical intervention in patients with symptomatic AS. One third of asymptomatic patients with severe AS will become symptomatic in 2 years with an estimated cardiac death of less than 1% each year to 5% each year.³ Patients with higher grades of AS severity seem to progress at a faster rate than lower grades of AS. After AS becomes moderate, aortic valve

TABLE 77-1 Severity of Aortic Stenosis According to Echocardiographic Criteria

Parameter	Mild	Moderate	Severe
Aortic valve area (cm ²)	1.6-2.5	1.1-1.5	≤1.0
Mean pressure gradient (mm Hg)	<20	20-39	≥40
Aortic jet velocity (m/sec)	2.0-2.9	3.0-3.9	≥4.0

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 129:e521-643, 2014.

area decreases on average by 0.1 cm² per year, the pressure gradient across the valve rises on average by 7 mm Hg per year, and the jet velocity increases by 0.3 m/sec per year.⁴⁻⁷

Indications for Surgery

The class I recommendations for aortic valve replacement (AVR) in patients with AS according to the American College of Cardiology (ACC) and the American Heart Association (AHA)¹ are the following:

1. Symptomatic patients with severe AS
2. Patients with severe AS undergoing concomitant coronary artery bypass graft (CABG) surgery, heart valve surgery, or aortic surgery
3. Patients with severe AS and left ventricular systolic dysfunction (ejection fraction < 50%)

The class IIa recommendations¹ for AVR are the following:

1. Asymptomatic patients with very severe AS (aortic jet velocity ≥ 5.0 m/sec or mean pressure gradient ≥ 60 mm Hg) and low surgical risk
2. Apparently asymptomatic patients with severe AS and an exercise test demonstrating decreased exercise tolerance or a fall in systolic blood pressure
3. Symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF (resting valve area ≤ 1.0 cm², aortic jet velocity < 4.0 m/sec or mean pressure gradient < 40 mm Hg, LVEF < 50%, and low-dose dobutamine stress study showing an aortic jet velocity ≥ 4.0 m/sec mean pressure gradient ≥ 40 mm Hg with a valve area ≤ 1.0 cm²)
4. Symptomatic patients with low-flow/low-gradient severe AS with an LVEF ≥ 50%, a calcified aortic valve with significantly reduced leaflet motion, and a valve area ≤ 1.0 cm² only if clinical, hemodynamic, and anatomic data support valve obstruction as the most likely cause of symptoms and data recorded when the patient is normotensive (systolic blood pressure < 140 mm Hg) indicate an aortic jet velocity < 4.0 m/sec or mean pressure gradient < 40 mm Hg, and a stroke volume index < 35 mL/m², and an indexed valve area ≤ 0.6 cm²/m².
5. Patients with moderate AS who are undergoing cardiac surgery for another indication.

The class IIb recommendation¹ for AVR is the following:

1. Asymptomatic patients with severe AS if the patient is at low surgical risk and serial testing shows an increase in aortic velocity of ≥ 0.3 m/sec per year.

AORTIC REGURGITATION

Isolated aortic regurgitation is the primary lesion for patients undergoing AVR in only a minority of patients ($\approx 10\%$ to 15%). Aortic valve repair is emerging as an attractive alternative to replacement in selected patients with aortic regurgitation. The details of epidemiology, pathophysiology, diagnosis, and treatment of aortic regurgitation are reviewed in the chapter on aortic valve repair.

AORTIC VALVE REPLACEMENT

Operative Techniques

The traditional and most common approach for an AVR is through a median sternotomy. After exposure of the heart, the patient is heparinized and cannulated. An aortic cannula is placed in the distal ascending aorta, and a two-staged venous cannula is placed in the right atrium. Aortic calcification may preclude safe ascending aortic cannulation, and alternative arterial cannulation, including femoral or axillary cannulation, may be considered. Deep hypothermia and circulatory arrest for management of the heavily calcified ascending aorta have been used, but they carry a significant risk of stroke. Alternate venous cannulation may be used if required for other concomitant procedures. Antegrade cardioplegia is typically used. However, retrograde cardioplegia delivery through the coronary sinus may be useful in the setting of severe aortic regurgitation, coronary disease, or LVH to supplement myocardial protection. A vent is placed through the right superior pulmonary vein. Following initiation of cardiopulmonary bypass and cardioplegic arrest, additional cardioplegia doses may be delivered in a retrograde fashion or directly through the coronary ostia. Patients with AS often have ventricular hypertrophy and may require larger cardioplegia volumes.

The aortotomy is started anteriorly and may be performed in a transverse fashion (in a plane parallel to and approximately 1 cm above the sinotubular junction) or may be an oblique one (starting with a transverse incision above the right coronary, but extending through the sinotubular junction and into the noncoronary sinus). Sufficient distance should be maintained from the right coronary artery to prevent injury during closure.

Retraction sutures are placed in the aortic wall above each commissure, and the distal aorta is retracted cephalad to facilitate exposure (Fig. 77-1). Valve excision is performed one cusp at a time, starting at the commissure between the right and noncoronary cusps and excising the right coronary cusp (Fig. 77-2). Next, the left coronary cusp is excised starting at the commissure between the left and right coronary cusps. The noncoronary cusp is then excised starting at the commissure between the

FIGURE 77-1 ■ Aortic valve exposure through a transverse aortotomy aided by three commissural sutures (arrows) and a suture retracting the distal portion of the ascending aorta cephalad.

left and noncoronary cusps. Use of a #11 blade for leaflet excision can permit complete decalcification by cutting around rather than through the calcified regions. Alternatively, after the valve is excised, débridement of calcium from the annulus is performed using forceps and rongeur. After satisfactory decalcification, the aortic root, ascending aorta, and left ventricle are irrigated to remove all free calcium deposits. During irrigation, care should be taken to prevent embolization of calcific debris into the coronary ostia.

Sizing may be performed before or after leaflet excision. In nondilated aortic roots, the sinotubular junction is typically the limiting factor in choosing the largest possible valve. The annulus is measured using commercial valve sizers, and an appropriate-sized valve is used (Fig. 77-3). If the annulus is too small, aortic root enlargement techniques may have to be performed (see next section).

There are two techniques to implant the valve: the continuous and the interrupted suture techniques. The continuous suture technique has fewer knots, which may save time and minimize foreign material left behind. Larger prosthesis may be implanted, as there is less “purse-stringing” effect on the tissues of the aortic root. However, this technique may be problematic if the aortic annulus is fragile or heavily calcified, or if there is suture dehiscence or breakage. The interrupted suture technique (Fig. 77-4) without the use of pledgets is our standard for implantation because it provides the maximum strength for prosthetic attachment, minimizes foreign material, allows placement of the largest possible

FIGURE 77-2 ■ Sharp excision of the aortic valve is performed using a #11 blade, starting with the right coronary cusp.

FIGURE 77-3 ■ Sizing of the appropriate aortic valve prosthesis using commercial sizers can be accomplished before (as depicted in this picture) or after valve excision.

prosthesis, and has low risk of paravalvular leak. Alternately colored, double-needle, 2-0 nonabsorbable, braided sutures are passed through the sewing ring of the prosthetic valve, and then through the native aortic annulus, from the ventricular to the aortic side, starting with the left coronary region, followed by the right coronary region, and then the noncoronary region (see [Figs. 77-4](#) and [77-5](#)). The sutures alternate in color (green and white) to simplify identification. Pledgets may be used if the aortic annulus is particularly fragile. The pledgets, using a horizontal mattress technique, are placed below the annulus, allowing the valve to sit above the annulus. The sutures are then passed through the sewing ring of the prosthetic valve, with attention paid to symmetrical spacing around the prosthetic valve. Alternatively, the needles are passed from above to below the annulus, placing the pledgets above and the valve below the annulus. Supra-annular positioning of the valve allows for a larger valve to be used. Great care must be exercised and judicious needle bites taken between the noncoronary and right coronary annuli and near the left coronary annulus because deep bites in these areas may cause heart block and left coronary artery injury, respectively.

After the valve is parachuted down ([Fig. 77-6](#)), all the sutures are then tied systematically starting with the left coronary cusp, followed by the right coronary cusp, and finally the noncoronary cusp ([Fig. 77-7](#)). The aortotomy is then closed in two layers using two running double-needle polypropylene sutures ([Fig. 77-8](#)). If the aortic tissue is thin and friable, Teflon felt or autologous pericardial strips may be used to reinforce the closure.

After the aortotomy is closed, de-airing maneuvers are performed. The aortic root vent is turned on, volume is

FIGURE 77-4 ■ Alternating green and white valve sutures are systematically passed through the aortic valve annulus and then through the sewing ring of the prosthetic valve traveling from the commissure between the left and right coronary cusps to the commissure between the left coronary and noncoronary cusps.

FIGURE 77-5 ■ All valve sutures have been placed around the annulus and through the sewing ring of the valve.

FIGURE 77-6 ■ The prosthetic valve is parachuted down into position by the surgeon who holds one set of valve sutures and the prosthetic valve along with the valve holder. The assistant holds the other two sets of valve sutures. The surgeon and assistant pull on the valve sutures while the surgeon parachutes the valve down into position.

FIGURE 77-7 ■ Picture of prosthetic aortic valve in position after tying all valve sutures systematically beginning with the left coronary cusp, followed by the right coronary cusp, and then the noncoronary cusp.

FIGURE 77-8 ■ Closure of the aortotomy can be performed using a one- (depicted in picture) or two-layer technique.

added to the heart, the pulmonary vent is temporarily turned off, the lungs are ventilated, and the left ventricle is gently massaged to displace the intracardiac air into the aortic root vent. After placing the patient in Trendelenburg position, the aortic cross-clamp is removed and the pulmonary vent resumed.

Using transesophageal echocardiography (TEE), paravalvular leak is ruled out, hemodynamic performance of the valve is assessed, and any remaining intracavitary air is detected and removed using additional de-airing maneuvers such as digitally tapping areas found to have a collection of air on TEE or allowing the heart to eject with the aortic root vent on suction. Alternatively, a needle can be used to aspirate the air through the left ventricular apex. All patients undergoing an AVR should receive both atrial and ventricular temporary pacing wires, as there is higher risk of atrioventricular blocks and other arrhythmias following this surgery. The patient is weaned from cardiopulmonary bypass, heparin is reversed with protamine, the cannulae are removed, and the incisions are closed in the usual fashion.

Aortic Root Enlargement

In patients with a small aortic annulus, implanting a small stented bioprosthetic valve or a mechanical valve may leave residual gradient across the aortic valve. Forcing a small prosthetic valve may result in perivalvular leak or disruption of the aorta or left ventricle. Ideally, the patient with a small aortic annulus should be identified preoperatively for optimal planning. However, in some cases precise sizing can only be achieved

intraoperatively. If there is a concern about the possibility of prosthesis-patient mismatch (see later), a root enlargement procedure may be performed. Alternatively, stentless tissue valves or mechanical valves, which have larger effective orifice areas, may be used.

Three different aortic root enlargement techniques have been described. Posterior enlargement of the aortic root (Fig. 77-9) is performed by either the Nicks-Nunez⁸ or the Rittenhouse-Manouguian⁹ technique, whereas anterior enlargement is performed using the Konno-Rastan^{10,11} aortoventriculoplasty technique.

Nicks-Nunez Technique

The Nicks-Nunez method (Fig. 77-10) of aortic root enlargement involves a vertical incision through the commissure between the left coronary and noncoronary cusp and extending down in the interleaflet triangle, followed by patch reconstruction of the aortic root. This method can enlarge the aortic root by 2-3 mm. If larger enlargement is needed, the incision must be extended beyond the interleaflet triangle into the anterior leaflet of the mitral valve and the left atrial roof. After making the incision, either an autologous pericardium or a prosthetic patch is fashioned into a diamond shape. One end of the patch is sewed onto the deep end of the enlarging incision at the level of the aortic-mitral continuity if the incision stopped at the interleaflet triangle. Interrupted pledgeted horizontal mattress sutures are used at the interleaflet triangle and the needles are passed through the sewing ring of the prosthetic valve. The rest of the valve sutures are placed through the aortic annulus as described above.

FIGURE 77-9 ■ Posterior enlargement of the aortic root using either the Nicks-Nunez or the Rittenhouse-Manouguian technique.

FIGURE 77-10 ■ A diamond-shaped patch of autologous pericardium or prosthetic material is fashioned. One end of the patch is inserted into the distal end of the enlargement using interrupted sutures with pledgets. At the level of the aortic annulus the sutures are passed through the sewing ring of the prosthetic valve. The remainder of the valve sutures are placed through the aortic annulus in a standard fashion.

FIGURE 77-11 ■ The diamond patch is then tailored for closure of the aortotomy. If a transverse aortotomy is used, then the patch is transected at the level of the transverse aortotomy and incorporated as part of the anastomosis of the aortic root to the ascending aorta.

If the enlarging incision was extended onto the anterior leaflet of the mitral valve and the left atrium, the diamond-shaped patch is similarly first sewed at the deepest end of the incision, repairing the mitral leaflet. Interrupted sutures without pledgets are used for the mitral leaflet portion. At the level of the annulus, interrupted pledgeted horizontal mattress sutures are passed through the annulus, then the patch, and lastly into the sewing ring of the prosthetic valve. After the valve is tied down, the remaining proximal end of the patch is tailored to close the aortotomy if an oblique incision is used (Fig. 77-11), or cut flat at the level of the transverse aortotomy and incorporated into the anastomosis of the ascending aorta to the aortic root.

Rittenhouse-Manouguian Technique

The Rittenhouse-Manouguian method of aortic root enlargement involves a vertical incision through the middle of the noncoronary sinus extending through the annulus and into the anterior leaflet of the mitral valve. After the incision is made, the patch reconstruction is similar to the Nick-Nunez technique described in the previous paragraph.

Konno-Rastan Technique

The Konno-Rastan method of aortic root enlargement is an anterior root enlargement technique, or aortoven-triculoplasty, whereby a vertical aortotomy is extended into the right coronary sinus left of the right coronary artery, through the aortic annulus near the commissure between the right and left coronary cusps, and into the interventricular septum. A second incision is performed on the right ventricular free wall (Fig. 77-12). After the two incisions are made, a diamond- and a triangle-shaped

FIGURE 77-12 ■ In the Konno-Rastan method of aortic root enlargement, an incision is made through the right coronary region of the aortic annulus, near the commissure between the left and right coronary cusps. The incision is carried further into the interventricular septum, and a similar incision is made on the right ventricular free wall.

patch are fashioned. One end of the diamond patch is sewed to the deep end of the incision in a continuous fashion to repair the interventricular septum up to the level of the aortic annulus (Fig. 77-13). Then the base of the triangular patch is attached using interrupted pledgeted mattress sutures to the diamond patch at the level of the annulus. The same sutures are also passed through the sewing ring of the prosthetic valve (Fig. 77-14). The rest of the valve sutures are placed through the valve annulus as described above. The triangular patch is then folded to cover the right ventricular outflow tract defect and sewed using continuous running suture. Finally, the left ventricular outflow tract patch is used to close the vertical aortotomy using continuous suture technique (Fig. 77-15).

FIGURE 77-13 ■ One end of a diamond patch is sewed to the deep end of the incision in a continuous fashion to repair the inter-ventricular septum up to the level of the aortic annulus.

FIGURE 77-14 ■ The base of a triangular patch is attached using interrupted pledgeted mattress sutures to the diamond patch at the level of the annulus. The same sutures are also passed through the sewing ring of the prosthetic valve.

FIGURE 77-15 ■ The triangular patch is then folded to cover the right ventricular outflow tract defect and sewed using continuous running suture. The left ventricular outflow tract patch is finally used to close the vertical aortotomy using continuous suture technique.

SPECIAL CONSIDERATIONS OF POSTOPERATIVE CARE

Postoperative care after AVR is similar to that of other types of cardiac surgery in most regards. However, one important factor to consider is that patients with AS commonly present with LVH, causing decreased left ventricular compliance. Reduction in compliance that occurs during cardiac surgery exacerbates the situation. Therefore, the left ventricle is highly dependent on higher than usual preload for sufficient filling. To that end, filling pressures (central venous pressure) should be kept between 15 and 18 mm Hg with intravenous volume infusions, rather than the usually accepted 8 to 10 mm Hg pressures. Atrial fibrillation, with consequent loss of atrial contractility, is less tolerated in these patients because they are losing up to 20% of their ventricular filling. Rhythm control strategies may be more beneficial in these patients.

OUTCOMES

Early Mortality

Early mortality after AVR is most commonly related to acute cardiac failure, neurologic complications, hemorrhage, and infection. The Society of Thoracic Surgeons (STS) National Database reports a 3.2% 30-day mortality for isolated AVR.¹² When adding CABG, mortality rises to 5.6%.¹³ Although, in the past, isolated reoperative AVR increased the risk of early mortality,^{14,15} it does not appear to do so in the current era.¹⁴ Early mortality has improved with time and continues to do so. In the 1990s early mortality for isolated AVR was approximately 4.3%¹⁵ compared with the more contemporary 3.2%.¹² Similarly, the early mortality of combined AVR and CABG improved significantly with time from 8.0%¹⁵ to 5.6%.¹³ Double valve surgery, including an AVR and either mitral valve or tricuspid valve replacement, raises the operative mortality to 11% to 14%.¹⁶ Triple valve

surgery, including AVR, mitral valve replacement, and tricuspid valve replacement, raises the operative mortality rate to higher than 15%.¹⁶ Risk factors for early mortality include increasing age, higher New York Heart Association (NYHA) functional class, LVH, left ventricular enlargement, presence of aortic regurgitation, renal dysfunction, severe chronic obstructive pulmonary disease (COPD), multiple reoperations, and concomitant CABG or heart valve surgery.¹⁷⁻²¹

Long-Term Survival

Late mortality can be divided into valve-related mortality and non-valve-related cardiac mortality. The former includes deaths caused by structural valve deterioration, nonstructural valve dysfunction, valve thromboembolism, bleeding, valve endocarditis, death related to a reoperation on an operated valve, or sudden and unexpected death in a patient with an operated valve. Non-valve-related mortality comprises other cardiac causes of death, such as progressive heart failure in a patient with a well-functioning prosthetic valve.²² The latter makes up 63% of all deaths in patients with mechanical valves and 59% of all deaths in patients with bioprosthetic valves at 15 years.²³ Although there does not appear to be a survival difference between patients with bioprosthetic and mechanical aortic valves at 10 years,²⁴ structural bioprosthetic valve deterioration leads to a survival benefit for patients with mechanical valves at 15 years follow-up.²³ In contrast, other research has shown that even at 15, 20, and 25 years, there is no survival difference between patients who receive bioprosthetic versus mechanical valves in the aortic position.^{15,21} Risk factors for late mortality include increasing age, higher NYHA functional class, LVH, left ventricular enlargement, left ventricular dysfunction, increased left atrial size, functional mitral regurgitation, atrial fibrillation, ventricular arrhythmia, renal dysfunction, diabetes mellitus, peripheral arterial disease, female gender, smoking, severe COPD, multiple cardiac reoperations, and concomitant CABG or heart valve surgery.^{17-21,25-27}

Early Complications

Neurologic Complications

The joint Society of Thoracic Surgeons/American Association for Thoracic Surgery (STS/AATS) panel subclassified cerebral embolic events into transient ischemic attacks (TIAs), which are fully reversible neurologic events lasting less than 24 hours; reversible ischemic neurologic deficit, which are fully reversible neurologic events lasting between 24 hours and 3 weeks; and strokes, which are nonreversible neurologic deficits lasting longer than 3 weeks.²² The rate of stroke for isolated AVR, according to the STS database, is 1.5%.¹² In high-risk (STS predicted risk of mortality > 10%) and older patients (>80 years old), the risk of stroke rises to between 2% and 4.4%.²⁸⁻³¹ The addition of CABG to the AVR also raises the risk to between 4.9% and 5.8%.^{32,33} Risk factors for early postoperative stroke include low LVEF (<40%), ascending aortic calcification, older than 70 years, female sex, diabetes mellitus, bypass time greater than 120

minutes, a history of stroke, carotid artery disease, and walking less than 300 meters during a 6-minute walk test.³⁴⁻⁴¹ The annual rate of late stroke is 1.3% and 1.4% for bioprosthetic and mechanical valves, respectively. Risk factors for late stroke include female sex, older than 75 years, atrial fibrillation, current or previous smoking, diabetes mellitus, and carotid artery disease.^{42,43} Most postoperative strokes (55% to 76%) occur within the first 24 to 48 hours after surgery, but the high-risk period likely lasts for 3 months after surgery.^{38,44-47} Postoperative stroke is a significant predictor of mortality, raising the mortality rate to 31% for those with early stroke (<24 h) and 14% for those with late stroke (>24 h) compared with the baseline 4.6% mortality rate in one study.³⁸ Although early strokes seem to be related to the operation, late strokes are more influenced by patient- and disease-related factors.⁴⁷

Approximately one third of patients who have undergone cardiac surgery experience postoperative delirium.⁴⁸ Preexisting organic mental disorders, significant prior alcohol consumption, advanced age, intracranial cerebral artery disease, and longer cardiopulmonary bypass time are risk factors for postoperative delirium.^{48,49} Perioperative medications such as opiates and sedatives are known contributors as well.⁴⁹

In one study, postoperative neurocognitive deficits detected on neuropsychiatric testing were identified in 38% of patients at discharge and 19% of patients at 3 months. These changes were not associated with clinically important differences in outcome or in quality of life.⁵⁰

Heart Block and Permanent Pacemaker Implantation

Atrioventricular node block occurs more frequently after heart valve surgery compared with other types of cardiac surgery, with 3% to 8% of patients requiring permanent pacemaker insertion.^{30,51,52} It is rather a unique feature of valve surgery, and it is because of the close proximity of the conduction system to the aortic valve in the area of the membranous septum. Judicious decalcification must be exercised and shallower needle bites must be taken at the level of the commissure between the non-coronary and right coronary cusps. Heart block may be transient because of edema of the tissues around the conduction system. However, if a patient remains pacer-dependent 7 to 10 days postoperatively, we recommend a permanent pacemaker insertion. Predictors of complete heart block and permanent pacemaker insertion include preoperative first-degree atrioventricular block or bundle branch block, postoperative cardiac arrest, combined aortic and mitral valve surgery, and infective endocarditis.⁵² The type of aortic valve prosthesis used was not an important predictor in one study.⁵²

Late Complications

Thromboembolism, Anticoagulation, and Bleeding Complications

Beyond the 3-month period after surgery when the risk of thromboembolism and bleeding is highest, the risk of

thromboembolism is approximately constant. The overall linearized rate of thromboembolism for mechanical aortic valves is quoted as 2 per 100 patient-years and approximately half of that for bioprosthetic aortic valves, according to one report.⁵³ In another report, the rates of thromboembolism are similar among various mechanical valves, ranging between 1.16% and 1.33%,⁵⁴ with one report quoting a lower rate for the On-X bileaflet mechanical valve (On-X Life Technologies Inc., Austin, TX) at 0.6% per year.⁵⁵ The rates are also comparable among different stented bioprosthetic valves, ranging between 0.78% and 1.22% per year.⁵⁴ However, the rate is much lower for allografts with a median of 0.23% per year.⁵⁴ Bleeding rates from anticoagulation appear to be independent of the prosthesis and range from 1% to 2% per year in a recent report.⁵⁴ Fluctuations in the international normalized ratio (INR) seem to be an important risk factor for both thromboembolic and bleeding events.^{56,57} Therefore, close monitoring of the INR to minimize fluctuations may be important to prevent these complications.⁵⁷ New point-of-care home testing may aid in achieving this goal.⁵⁸ Anticoagulation with a minimum target INR of 2.0 to 3.0 for low-risk patients and valves with low thrombogenicity (bileaflet valves) is recommended for mechanical AVR.⁵⁹⁻⁶¹ However, interim results from the first limb of the Prospective Randomized On-X Anticoagulation Clinical Trial (PROACT) suggest that INR may be safely maintained between 1.5 and 2.0 with lower risk of bleeding and without a significant increase in thromboembolism.⁶² The target INR should be 2.5 to 3.5 for patients at high risk for thromboembolism or who receive mechanical valves with high thrombogenicity (disc valves). For bioprosthetic AVR, the bulk of the evidence favors no anticoagulation in patients at low risk for thromboembolism because antiplatelet therapy suffices in this patient population.^{46,63-70} The recommendations are shifting from anticoagulation in the first 3 months followed by antiplatelet therapy thereafter in low-risk patients to only antiplatelet therapy right after surgery.⁵⁹⁻⁶¹ Patients at high risk for thromboembolism should have a different consideration and anticoagulation may be warranted in this group.

Prosthesis thrombosis is a serious but rare complication of AVR that occurs in less than 0.2% of cases per year.⁷¹ It is more common in mechanical valves. Although often ineffective, thrombolysis may be attempted in patients with heart failure caused by valve dysfunction and who are considered too high risk for surgery.⁷² Surgical thrombectomy or re-replacement of the prosthetic valve is usually required and is associated with a high mortality rate of 10% to 15%.^{71,72}

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis (PVE) is a serious complication of AVR and is divided into early PVE if it occurs less than 60 days post implantation and late PVE if it occurs more than 60 days post implantation. The rate of PVE is approximately 0.5% to 1% per year, with a slightly higher rate in the first 6 to 12 months compared to less than 12 months.⁷³⁻⁷⁶ Early PVE is usually a result of perioperative seeding of the prosthetic valve either

intraoperatively or from wound infections or indwelling intravascular catheters postoperatively. Late PVE usually results from noncardiac sources of bacteremia or sometimes from insidious infections with less virulent organisms introduced perioperatively. The microbiological profile of early PVE includes *Staphylococcus aureus*, *S. epidermidis*, gram-negative bacteria, and fungal infections. For late PVE, the microbiological profile resembles that of native endocarditis and includes *Streptococcus* and *Staphylococcus* species. Patients presenting with fever after an AVR should be thoroughly investigated for PVE. Serial blood cultures and transthoracic or transesophageal echocardiography are important components of the diagnostic workup. Surgical indications for the management of PVE include early PVE, valve dysfunction including dehiscence or paravalvular leak, associated heart failure, presence of new conduction defect, abscess, aneurysm or fistula, persistent bacteremia despite maximum and appropriate medical therapy, vegetations larger than 10 mm in size, systemic embolization, all fungal infections, and virulent strains of *S. aureus*, *Serratia marcescens*, and *Pseudomonas aeruginosa*. The timing of surgery has been an area of debate. Sterilization of the valve is ideal before reoperation and is more likely if the vegetation is limited to the leaflets without annular involvement. Strokes from septic emboli are a common occurrence in patients with PVE, and differentiating ischemic stroke from hemorrhagic stroke is important because the former does not adversely affect outcome after reoperation whereas the latter does.⁷⁷ Computed tomography is an important modality in patients with neurologic signs or symptoms of stroke. The outcome following PVE is poor. Early PVE is associated with 30% to 80% mortality, whereas late PVE is associated with 20% to 40% mortality.⁷⁸

Structural Valve Deterioration and Freedom from Reoperation

In the quest for the ideal valve, new valves are constantly being introduced to the market after testing and short-term clinical trials, making the choice between different valves for AVR a challenge. An in-depth discussion of the different valve types is found in Chapter 76. We limit the discussion in this section to structural valve deterioration (SVD) and freedom from reoperation of mechanical and bioprosthetic valves in the aortic position. Third-generation bileaflet mechanical valves have high structural integrity, and SVD is not observed or reported in several large series totaling more than 50,000 patient-years of follow-up.⁷⁹⁻⁸² The durability of these valves is excellent, resulting in a freedom from reoperation of approximately 94% at 10 years⁸² and in one report up to 98% at 25 years after surgery.^{79,83}

Glutaraldehyde-treated biological valves are subject to degenerative changes and calcification with time. Therapies to mitigate these processes help to slow down SVD and include using compounds such as surfactants, alpha oleic acid, and ethanol. The use of bioprosthetic valves has increased dramatically over the past couple of decades, increasing from 42% in 1996 to 82% in 2011.⁸⁴ Although the risk of thromboembolism and anticoagulation-related

bleeding events is lower in bioprosthetic valves, the concern about higher rates of SVD and perhaps higher rates of PVE remains.⁸³ Surgeons must therefore balance between the risks and benefits of various valve choices. There is no convincing evidence to suggest that various second-generation pericardial and porcine bioprostheses differ in longevity; therefore, choice of the valve should depend on surgeon comfort and institutional preferences. Age is an important contributing factor to SVD in patients with bioprosthetic valves. Younger patients seem to have an accelerated rate of SVD probably as a result of a combination of factors, such as calcium metabolism and hemodynamics. In all series, patients older than 70 years have a greater than 90% freedom from reoperation at 15 to 25 years. This rate falls slowly in patients 60 to 70 years old, and precipitously in patients younger than 60 years.⁸⁵⁻⁹⁶ Actuarial freedom from reoperation in these studies probably overestimates the rate of SVD compared with actual freedom. In a recent report, the reoperation rate was 4% at 25 years after bioprosthetic AVR, with 2.6% due to SVD.⁸⁸

Paravalvular Leak and Hemolysis

The continuous suture technique of aortic valve implantation was traditionally thought to be a risk factor for paravalvular leak compared with an interrupted suture technique. However, recent reports show no difference in the rate of paravalvular leak between the two suture techniques.⁹⁷⁻⁹⁹ In the absence of infection, important paravalvular leak in mechanical or bioprosthetic aortic valves is uncommon, although minor leaks may occur.¹⁰⁰ A contemporary report quotes a 0.01% annual rate.⁷⁹ If a paravalvular leak occurs, it can usually be detected in the first few months after surgery.⁷³ There may be an anatomic predisposition in the area extending from the right and noncoronary commissure to one third the distance along the right coronary cusp in one direction and two thirds the distance along the noncoronary cusp in the other direction.¹⁰¹ Minor hemolysis may be managed conservatively, whereas clinically significant hemolysis requires surgical intervention.

Symptomatic Relief

Most surviving patients experience significant functional improvement after an AVR, with 70% to 90% of patients in NYHA functional classes II through IV becoming class I.¹⁰² Even 10 years after surgery, 90% of patients remain in NYHA class I or II.

Left Ventricular Remodeling

Increased left ventricular mass (LVM) is a common occurrence later in patients with aortic valve disease, either through concentric LVH in AS or through left ventricular dilation and eccentric hypertrophy in aortic regurgitation. Increased LVM is a strong negative prognostic factor in aortic valve disease.^{103,104} AVR relieves the left ventricular pressure and volume overload in AS and aortic regurgitation, allowing the left ventricular myocardium to remodel and the LVM to regress. Left

ventricular remodeling occurs in the first 18 months after surgery but can last up to 5 years.¹⁰⁵⁻¹⁰⁷ However, in patients with decreased left ventricular contractility, signifying late-stage aortic valve disease, or reduced exercise capacity preoperatively, remodeling may fail to occur.^{106,108-111} Myocardial gene expression of microRNA-133a (miR-133a) is currently being explored as a potential predictor of left ventricular remodeling in patients with AS, with several reports demonstrating promising results.¹¹²⁻¹¹⁴ Further research may clarify the role of miR-133a in AVR decision making, especially in asymptomatic patients with signs of LVH. The presence of prosthesis-patient mismatch may also hinder LVM regression, as discussed in the next subsection.

Prosthesis-Patient Mismatch

The theoretical goal of an AVR is to reduce the pressure and volume overload on the left ventricle. Although transprosthetic gradients postoperatively should be minimal to allow left ventricular remodeling, high gradients are occasionally seen despite an appropriately functioning valve. The persistence of left ventricular outflow obstruction postoperatively is termed *prosthesis-patient mismatch* (PPM).^{115,116} The parameter that most consistently correlates with postoperative transprosthetic gradients is the effective orifice area (EOA) indexed to the patient's body surface area or, indexed effective orifice area (IEOA).¹¹⁶ The EOA is measured by echocardiography using the continuity equation or by cardiac catheterization using the Gorlin formula. An IEOA of 0.65 to 0.85 cm²/m² is generally defined as moderate PPM, and less than 0.65 cm²/m² is defined as severe PPM. The prevalence of moderate PPM ranges from 20% to 70% and severe PPM ranges from 2% to 11%.¹¹⁵ The significance of PPM is a controversial topic and may depend on the definition of PPM used in various studies. Some studies have shown that PPM does not influence mid-term and long-term survival or left ventricular mass at mid-term follow-up.^{18,117,118} In contrast, other groups have shown that PPM after AVR is associated with less improvement in functional status, less regression of LVH, higher risk of congestive heart failure, and increased long-term mortality.¹¹⁹⁻¹²³ Patients with left ventricular dysfunction, including low-gradient AS, and younger patients (<60 years) who may be more active are particularly susceptible to PPM.^{119,124-127} Several options exist if a surgeon anticipates PPM in a large patient with a small aortic annulus. In young active patients or patients with left ventricular dysfunction (ejection fraction < 50%) choosing prosthetic valves with larger IEOAs according to manufacturer-available user-friendly charts is one option. Aortic root enlargement is another method to allow for the implantation of larger prosthetic valve sizes. However, in older and sedentary patients, the extra risk in performing aortic root enlargement may not be worth the benefit of the extra valve size, and a certain amount of PPM may need to be accepted.¹²⁸

Valve-Related Complications

CONCLUSION

Aortic valve replacement remains the gold standard for the treatment of severe aortic valve disease. However, valve repair is emerging as a feasible and attractive alternative to valve replacement in selected patients. Valve repair can reduce or eliminate the risks of prosthesis-related complications including thromboembolism, endocarditis, anticoagulant-related hemorrhage, and reoperation owing to structural valve deterioration among others. Analogous to the mitral valve, a reconstructive approach to the aortic valve requires a thorough and detailed understanding of three-dimensional valve anatomy, valve function, assessment and classification of pathologic lesions, and treatment of all affected components of the valve. In this chapter, we review the key features of aortic valve insufficiency, aortic valve and root anatomy, an approach to valve assessment and lesion classification, and a demonstration of commonly used reparative techniques for aortic valve repair. Furthermore, we review the outcomes of aortic valve repair in unselected cohorts and in distinct subsets of patients undergoing aortic valve preservation and repair.

AORTIC REGURGITATION

Epidemiology and Etiology

The causes of aortic regurgitation (AR) are numerous and can be attributed to a disturbance in any of the components of the functional unit of the aortic valve (e.g., cusps, sinuses of Valsalva, sinotubular junction, ventriculoaortic junction). In general, the causes can be divided into those that affect the valve cusps (e.g., calcific degeneration, congenitally bicuspid valve, infective endocarditis, rheumatic disease, myxomatous degeneration) and those that affect the aortic root (e.g., aortic dissection, aortitis of various etiologies such as syphilis, connective tissue disorders such as Marfan syndrome).

Pathophysiology

The pathophysiology of AR is dependent on the acuity of onset and duration of the disease process. In acute AR, typically caused by aortic dissection, infective

endocarditis, trauma, or valve prosthesis failure, there is a sudden increase in left ventricular end-diastolic volume because of the regurgitation. Since the left ventricle has limited compliance and does not have time to adapt, the left ventricular end-diastolic pressure (LVEDP) rises rapidly.

In chronic AR, there is a slow and insidious progression of left ventricular (LV) dilation and eccentric hypertrophy because of an increase in left ventricular end-diastolic volume, LVEDP, and wall stress. Dilation of the LV, while maintaining normal systolic function, increases total stroke volume and maintains forward flow.¹ This increase in stroke volume coupled with an increase in LVEDP is associated with the wide pulse pressure typical of chronic AR. Eventually, the hypertrophic response is exhausted, and LVEF drops as afterload increases, leading to heart failure and its associated clinical presentation.^{2,3}

Clinical Features

Patients with acute AR usually exhibit sudden or rapidly progressive cardiovascular collapse, which can be life threatening if not addressed promptly. They often exhibit ischemic symptoms because of the decrease in coronary blood flow and increased myocardial oxygen demand. In contrast, patients with chronic AR are asymptomatic for a long period of time because of the compensatory LV changes discussed earlier. Once the compensatory response is exhausted, the patients start having heart failure symptoms such as exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Patients may also feel palpitations and angina.

The classic murmur of AR is an early diastolic, blowing, decrescendo murmur heard best at the level of the diaphragm at the left sternal border while the patient is sitting, leaning forward, and in deep exhalation. It may become holodiastolic in severe AR, and isometric exercises tend to accentuate the murmur. Classic signs of widened pulse pressure may also be found, including Corrigan or water-hammer pulse, De Musset sign (bobbing of the head with heart beats), Quincke pulse (pulsations of the lip and fingers), Traube sign (pistol shot sounds over the femoral artery), and Müller sign (pulsations of the uvula).

Diagnostic Criteria

Transthoracic echocardiography with Doppler color-flow is the most useful tool for the diagnosis of AR.⁴ The jet width and vena contracta width on Doppler color-flow are used to qualitatively assess the severity of AR, whereas the regurgitant volume, regurgitant fraction, and regurgitant orifice area are used for the quantitative assessment.

Indications for Surgery

Decision making for surgical intervention for aortic valve surgery needs to incorporate the natural history of medically managed disease, the risks associated with surgical intervention, and longer-term risks that might accrue

related to prosthetic valve implantation. The class I recommendations for aortic valve intervention in patients with AR according to the 2014 American College of Cardiology and the American Heart Association⁵ are the following: symptomatic patients with chronic severe AR, asymptomatic patients with chronic severe AR and LV dysfunction (ejection fraction < 50%) at rest, and patients with chronic severe AR who are undergoing concomitant coronary artery bypass grafting, aortic surgery, or other heart valve surgery.

The class IIa recommendation is for patients with asymptomatic AR and normal LV systolic function (ejection fraction > 50%) but with severe LV dilation (end-systolic diameter > 50 mm). The class IIb recommendation is for patients with moderate AR who are undergoing coronary artery bypass grafting, aortic surgery, or other heart valve surgery. Aortic valve intervention may also be reasonable in asymptomatic patients with chronic severe AR, normal LV systolic function, and severe LV dilation (end-diastolic diameter > 65 mm) if the operative risk is low. Other considerations can include evidence of progressive LV dilation, declining exercise tolerance, or abnormal hemodynamic response to exercise.

However, aortic valve repair carries a similar, if not lower, risk of perioperative complication with a low risk of valve-related events over time. Similar to mitral valve repair for mitral regurgitation,⁶ there is some suggestion that aortic valve intervention should be considered earlier in patients in whom aortic valve repair is likely.⁷

Another broad category of patients who undergo aortic valve preservation and repair are those with primary aortic pathology involving the aortic root and/or the ascending aorta and varying degrees of associated aortic valvular disease. In these patients, the primary indication for intervention is driven by aortic size, discussed in the American,⁸ European,⁹ and Canadian Guidelines.¹⁰

From a technical perspective, all patients with primary aortic insufficiency are potentially candidates for repair. However, the success of aortic valve repair is determined largely by the quality of cusp tissue available. Thus, patients with significant leaflet calcification, destruction owing to active endocarditis, or rheumatic involvement are least likely to undergo successful and durable aortic valve repair.¹¹ In contrast, repair has been shown to have good results in patients with bicuspid^{12,13} (and in smaller series, unicuspid,¹⁴ and quadricuspid¹⁵) aortic valves, despite the abnormalities in cusp anatomy. An important limitation to the universal application of aortic valve repair techniques is the lack of surgical expertise and experience in this field; however, this is changing rapidly with increasing interest in aortic valve repair. Patients who are candidates for repair should be referred to centers with appropriate expertise.

AORTIC VALVE ANATOMY AND FUNCTION

The anatomy of the aortic valve and root is familiar to cardiac surgeons.¹⁶ However, there are some features outlined here that are particularly relevant to aortic valve preserving and repair surgery.¹⁷ Like the mitral valve,

FIGURE 78-1 ■ Anatomy of the aortic valve and the functional aortic annulus. STJ, Sinotubular junction; VAJ, ventriculo-aortic junction.

aortic valve function involves an important interaction between the valve annulus and leaflets. Importantly, however, the annulus of the aortic valve is not a single structure but rather consists of three different components—namely, the sinotubular junction, the ventriculo-aortic junction, and the anatomic crown-shaped annulus, which serves as the insertion point of the aortic valve cusps¹⁸ (Fig. 78-1). These components work together to facilitate normal valve function and together are termed the *functional aortic annulus*. The aortic valve leaflets insert into the aortic annulus proximally at the ventriculo-aortic junction (VAJ) and distally at the sinotubular junction (STJ). In a normal aortic valve, the cusps coapt at the center of the aortic valve orifice with a coaptation height that is approximately at the mid-level between the VAJ and the STJ. The height of the sinuses of Valsalva (from the VAJ to the STJ) corresponds to the external diameter of the STJ, which can be useful to size prostheses for aortic root replacement and to assess cusp geometry after aortic valve repair.

As a functional entity, the aortic valve consists of the functional aortic annulus (FAA), and the valve cusps. The integrity of these two functional components is the basis for good valvular function, and alteration in one of these components is frequently associated with alteration in the other. Thus, a fundamental principle in aortic valve repair is that lesions of the cusps and the FAA should both be addressed at the time of valve repair.

The anatomy of the subvalvular region of the aortic valve and its surrounding structures also has important implications for aortic valve repair¹⁹ (Fig. 78-2). An important observation is that external dissection of the aortic root from its surrounding structures is limited by the membranous septum (at the junction of the noncoronary [NC] and right coronary [RC] cusps) and by ventricular muscle (at the junction of the left coronary [LC] and RC cusps), whereas at all other points, external dissection down to the level of the anatomic valve annulus is possible and necessary when valve-sparing root replacement is performed using the reimplantation technique. Thus, the proximal suture line for the aortic valve

FIGURE 78-2 ■ Anatomy of the subvalvular region of the aortic valve. The dotted line marks the limits of external dissection of the aortic root and the proximal suture line for a valve-sparing root replacement procedure using the reimplantation technique. LCC, Left coronary cusp; NCC, noncoronary cusp; RCC, right coronary cusp.

reimplantation procedure follows these external limitations in a curvilinear fashion.

CLASSIFICATION OF AORTIC INSUFFICIENCY

Until recently, a major limitation to the more generalized application of aortic valve repair techniques was the absence of a common framework for valve assessment to help guide the approach to valve repair. Important lessons in this regard can be learned from the development of mitral valve repair. The Carpentier classification²⁰ of mitral valve insufficiency was responsible, in large part, for the development and generalized dissemination of repair techniques for the mitral valve because it provided a common language for cardiologists, anesthesiologists, and surgeons to communicate about disease mechanisms and pathology. Key characteristics of that classification system were that it encompassed the entire spectrum of disease, it clarified and provided insight into the mechanism of insufficiency, it could be consistently applied using different assessment modalities (i.e., echocardiography and surgical assessment), it guided the repair techniques, and it provided a framework for the assessment of long-term outcome for differing mitral valve pathologies.

Over the past decade, a similar classification of aortic valve insufficiency has been developed with the above characteristics in mind¹¹ (Fig. 78-3). This classification centers on the idea that the aortic valve, much like the mitral valve, consists of two major components: the aortic annulus and the valve leaflets. Contrary to the mitral valve, however, the annulus of the aortic valve is not a single anatomic structure. The functional aortic annulus consists of two separate components, namely the ventriculoaortic junction and the sinotubular junction. As in Carpentier's classification of mitral valve disease,

AI Class	Type I Normal cusp motion with FAA dilation or cusp perforation				Type II Cusp prolapse	Type III Cusp restriction
	Ia	Ib	Ic	Id		
Mechanism						
Repair Techniques (Primary)	STJ remodeling <i>Ascending aortic graft</i>	Aortic valve sparing: <i>Reimplantation or Remodeling with SCA</i>	SCA	Patch repair <i>Autologous or bovine pericardium</i>	Prolapse repair <i>Free margin plication Triangular resection Free margin resuspension</i>	Leaflet repair <i>Shaving Decalcification Patch</i>
(Secondary)	SCA		STJ annuloplasty	SCA	SCA	SCA

FIGURE 78-3 ■ Repair-oriented classification of aortic insufficiency. FAA, Functional aortic annulus; SCA, subcommissural annuloplasty; STJ, sinotubular junction.

regurgitation associated with normal leaflet motion is designated as type I. This is largely due to lesions of the functional aortic annulus with type Ia aortic insufficiency (AI) owing to sinotubular junction enlargement and dilation of the ascending aorta, type Ib owing to dilation of the sinuses of Valsalva and the sinotubular junction, type Ic owing to dilation of the ventriculoaortic junction, and lastly type Id owing to cusp perforation without a primary functional aortic annulus lesion. Type II AI is due to leaflet prolapse secondary to excessive cusp tissue or due to commissural disruption. Type III AI is due to leaflet restriction, which can be found in bicuspid, degenerative, or rheumatic valvular disease because of calcification, thickening, and fibrosis of the aortic valve leaflets.

Patients can exhibit either single or multiple lesions contributing to their aortic insufficiency. For example, patients with isolated type Ib AI (owing to dilation of the sinuses of Valsalva) are expected to have a central regurgitant jet. Thus, the presence of a sinus of Valsalva aneurysm with an eccentric AI jet suggests concomitant leaflet prolapse (type II) or restriction (type III). Further assessment of leaflet anatomy can help to better delineate the different mechanisms contributing to AI. Once the mechanism of AI is well understood, the classification system can help to guide the surgeon in the choice of surgical techniques for correction of the pathology.

SURGICAL TECHNIQUES

Exposure and Assessment

Aortic valve repair procedures are generally performed through a median sternotomy. Arterial cannulation is performed distal to any diseased aortic segments, typically in

the distal ascending aorta or aortic arch. Alternatively, axillary artery cannulation may be performed in the setting of aortic arch pathology. A single, two-stage venous cannula is inserted through the right atrial appendage unless alternative cannulation strategies are required to treat coexisting pathology. After cardioplegia, a transverse aortotomy is performed approximately 1 cm above the sinotubular junction starting above the NC sinus and the posterior 2 to 3 cm of aortic wall is left intact. The distal aorta is retracted cephalad. Full-thickness 4-0 polypropylene traction sutures are placed at the three commissures and retracted using clamps, but not tied, to permit a dynamic assessment of valve anatomy. Axial traction is applied (perpendicular to the level of the annular plane) on the commissural traction sutures. This maneuver demonstrates physiologic aortic valve closure position, and the area and height of coaptation is observed. Leaflets are inspected to assess mobility, restriction, calcification, and prolapse. A prolapsing cusp will exhibit a transverse fibrous band at this time, which is also visible on echocardiography¹⁷ (Fig. 78-4).

Interventions on the Aortic Root and Annulus

Type 1 lesions are most frequently due to dilation of the various components of the functional aortic annulus; they can occur in isolation or in association with cusp disease. A type Ia lesion occurs because of a supracoronary ascending aortic aneurysm with concomitant dilation of the STJ. This is corrected by replacing the ascending aorta and remodeling the STJ using a Dacron tube graft. When significant associated AI is present, subcommissural annuloplasty is also performed. Aneurysms of the aortic root (type Ib) are frequently associated with

FIGURE 78-4 ■ A and B, A transverse fibrous band is typically visible on echocardiography (arrow) and surgical inspection (C, D) in the setting cusp prolapse in trileaflet aortic valves and may help in the detection and localization of cusp prolapse.

dilation of the STJ and the VAJ. These aneurysms are treated using valve-sparing root replacement, preferentially using the reimplantation technique²¹ because it provides better stabilization of the VAJ. Aortic root remodeling²² can also be used to treat aneurysms of the aortic root, and it is particularly useful when only one or two sinuses are involved or in patients in whom there is no risk of ongoing VAJ dilation.

Subcommissural Annuloplasty

Subcommissural annuloplasty is typically performed at midcommissural height, except at the NC/RC commissure, where it should be performed higher to avoid the membranous septum and conduction tissue (Fig. 78-5). Care should also be taken in this area during tying of the suture, to avoid a tear in the septum. At the other two commissures, the subcommissural annuloplasty can be performed at a lower level if a greater increase in the coaptation surface is desired. A subcommissural annuloplasty reduces the width of the interleaflet triangle, improves cusp coaptation, and can help to stabilize the

FIGURE 78-5 ■ Subcommissural annuloplasty.

ventriculoaortic junction. In the setting of a bicuspid aortic valve, however, subcommissural is not always sufficient for the prevention of future VAJ dilation.⁴⁹

Valve-Sparing Root Replacement: Reimplantation Technique

A valve-sparing root replacement using the reimplantation technique provides the most stable form of functional aortic annuloplasty. In addition to being used in patients with aortic root aneurysms, this technique can also facilitate aortic valve repair in patients with moderate root dilation in the setting of bicuspid aortic valves. Originally pioneered by David and colleagues, multiple modifications of this procedure have been reported. The important steps of this procedure are described below.²³

Aortic Root Preparation. The key principle is to dissect the aortic root externally as low as possible, given the natural anatomic limitations (i.e., where the root inserts into ventricular muscle). The root dissection is started along the NC sinus and continued towards the LC/NC commissure. In this area, the subannular region of the aortic valve is fibrous and dissection can therefore be

carried to below the level of insertion of the leaflets. Moving toward the RC/NC commissure and along the right sinus and the RC/LC commissure, the dissection is limited by nonfibrous portions of the annulus (Fig. 78-6). The sinuses of Valsalva are then resected leaving approximately 5 mm of aortic wall attached and the coronary buttons are harvested.

Prosthesis Sizing. The three commissural traction sutures are pulled perpendicular to the annular plane with a slight inward motion to ensure good leaflet coaptation. When the leaflets are coapting adequately, a Hagar dilator is used to size the circle that includes the three commissures, and a graft 4 mm larger is chosen as this graft will sit outside the commissural posts. An alternative approach to prosthesis sizing takes advantage of the principle that in a normally functioning aortic valve, the height of the commissure (measured from the base of the interleaflet triangle to the top of the commissure) is equal to external diameter of the sinotubular junction²⁴ (Fig. 78-7). Although various components of the aortic root and the functional aortic annulus may dilate in the setting of root aneurysms, the height of the commissure remains relatively constant. The height of the commissure is most

FIGURE 78-6 ■ External dissection for a valve-sparing root replacement procedure using the reimplantation technique.

FIGURE 78-7 ■ A novel method for prosthesis sizing when using the reimplantation technique. *LCC*, Left coronary cusp; *NCC*, non-coronary cusp.

FIGURE 78-8 ■ Proximal suture line for a valve-sparing root replacement procedure using the reimplantation technique.

easily measured at the NC/LC commissure by first drawing a connecting line between the nadirs of the two adjacent cusps (base of interleaflet triangle) and measuring the distance between this line and the top of the commissure. This height corresponds to the diameter of the graft chosen.

Proximal Suture Line. 2-0 Tycron sutures with pledgets are passed from inside to outside the aorta with the pledgets on the inside, starting from the NC/LC

commissure and moving clockwise. Along the fibrous portion of the aortic annulus, these sutures are inserted along the horizontal plane formed by the base of the inter-leaflet triangles. Importantly, however, along the nonfibrous portions of the annulus where the external dissection of the aortic root is limited by muscle, these sutures are inserted along the lowest portion of the freely dissected aortic root, making the proximal suture line slightly higher at the RC/NC and RC/LC commissures compared with the LC/NC commissure (Fig. 78-8).

FIGURE 78-9 ■ Tailoring of the prosthesis for the reimplantation technique.

Prosthesis Preparation and Fixation. A Dacron prosthesis with or without built-in neoaortic sinuses can be used. The three commissures are attached to the prosthesis along the same plane—the new sinotubular junction. Because of external limitations of root dissection, the graft has to be tailored. First, the distance from the base of the interleaflet triangle to the top of the commissure is measured at the LC/NC commissure and marked on the graft. Next, at the RC/NC and RC/LC commissures, the distance from the proximal suture to the top of the commissure is measured and used to determine the amount of graft material that needs to be trimmed (Fig. 78-9). The pledgeted sutures are then passed through the base of the prosthesis, respecting the spaces between sutures and the curvilinear contour of the suture line. The commissural traction sutures are pulled up together while tying down the prosthesis to ensure appropriate seating around the aortic annulus.

Valve Reimplantation. The commissures are reimplanted first using 4-0 polypropylene sutures while pulling up on the prosthesis and the native commissure and then tied into place. This running suture line is performed in small regular steps passing the suture from outside the prosthesis to inside and through the aortic wall, staying close to the annulus, and then back out of the prosthesis.

Leaflet Assessment and Repair. After valve reimplantation, it is critical to reexamine the leaflets for any unmasked prolapse, symmetry, and the height and depth of coaptation. Prolapse can be repaired using a variety of techniques described later. Cardioplegia is administered through the distal end of the graft with partial clamping to distend the new aortic root and to assess root pressure and signs of LV dilation. A limited echocardiographic view can be obtained at this time. The cardioplegia solution is then slowly aspirated out of the prosthesis without distorting the leaflets. This gives another visual assessment of the aortic valve in its physiologic closed state as well as the area and height of coaptation. Coronary ostia

are then reimplanted on the graft, and the distal anastomosis is performed at the level of normal aorta.

Alternative Approaches to Aortic Valve Annuloplasty

The reimplantation technique provides the most stable form of annuloplasty of the aortic valve and allows the surgeon to modulate a variety of parameters, including the VAJ, STJ, and cusp and commissural orientation; however, it involves extensive dissection of the aortic valve, root, and surrounding structures, and it necessitates reimplantation of the coronary ostia. In patients with normal-sized aortic roots and dilation of the VAJ, use of the reimplantation procedure for annuloplasty is controversial and can expose the patients to unnecessary risk. Therefore, alternative approaches to annuloplasty of the aortic valve, without root replacement, are currently under development and in various stages of evaluation. External annuloplasty is the most frequently used option using a flexible ring.²⁵ This option is typically used as an adjunct to the remodeling technique for aortic root replacement to provide more VAJ support, but in theory can be used in isolation as well. An important limitation to the external annuloplasty is the inability to place the external ring at the level of the true VAJ because of the limits of external dissection. To overcome this limitation, a number of different internal annuloplasty systems are currently being developed.^{26,27} A suture-based internal VAJ annuloplasty using a large-caliber PTFE suture has also been proposed. However, results of these techniques on long-term valve function are lacking.

Cusp Repair Techniques

Cusp prolapse is the most frequently encountered lesion and is associated with excess length of the free margin, which can be corrected using either central free margin plication or free margin resuspension. When a single cusp is prolapsing, the two nonprolapsing cusps serve as the reference and are used to estimate the required reduction in the free margin length. When two cusps are prolapsing, the third nonprolapsing cusp is used as a reference to indicate the desired height of coaptation. In the rare instance that all the cusps are prolapsing, the goal is to achieve a cusp coaptation height at the midlevel of the sinuses of Valsalva. Alternatively, calipers that permit measurement of effective cusp height can be used.²⁸

Free Margin Plication

The technique for central free margin plication has been described previously²⁹ (Fig. 78-10). A 7-0 polypropylene suture is passed through the center of the two nonprolapsing reference cusps, and gentle axial traction is applied. The prolapsing cusp is gently pulled parallel to the reference cusp, and a 6-0 polypropylene suture is passed through the prolapsing cusp, from the aortic to ventricular side, at the point at which it meets the center of the reference cusp. Next, the direction of traction on the prolapsing cusp is reversed, and the same suture is passed from the ventricular to the aortic side of the cusp

FIGURE 78-10 ■ Free margin plication technique for the correction of cusp prolapse.

where it meets the middle of the reference cusp. The length of cusp free margin between the two ends of this 6-0 suture represents the quantity of excess free margin, which is then plicated by tying this suture with the excess tissue on the aortic side.

The plication is extended by 5 to 10 mm onto the body of the aortic cusp by adding interrupted or running locked 6-0 polypropylene sutures. If there is significant excessive tissue, it can be shaved off using a scalpel or scissors, keeping sufficient tissue to bring the edges together.

Free Margin Resuspension

Excess length of the cusp free margin can also be corrected using resuspension with polytetrafluoroethylene (PTFE) suture^{30,31} (Fig. 78-11). A 7-0 polypropylene suture is first passed through the center (nodule of Arantius) of the two nonprolapsing cusps, which serves as a reference. A 7-0 PTFE suture is passed twice at the top of the commissure. Next, one arm of the suture is passed over the length of the free margin in a running fashion. The suture is locked at the other commissure. A second 7-0 PTFE is then passed in the same fashion along the cusp free margin. The length of the free margin is reduced by applying gentle traction on each branch of the PTFE sutures and applying opposite resistance with a forceps at the middle of the free margin. This maneuver is used to plicate and shorten the free margin until it reaches the same length as the adjacent reference cusp free margin.

The same maneuver is applied for the second half of the free margin. This two-step technique for free margin resuspension allows symmetric and homogenous shortening. When the appropriate amount of free margin shortening is achieved, the two suture ends at each commissure are tied.

This technique can be used in isolation or in combination with other cusp repair techniques, and it is particularly useful in the setting of a fragile free margin with multiple fenestrations or to homogenize the free margin when a pericardial patch is used for cusp augmentation.

Cusp Shaving, Resection, and Patch Use

In contrast to cusp prolapse, management of restrictive cusp pathology owing to localized calcification, inflammatory or rheumatic disease, or bicuspid valve with restrictive raphe (discussed later) can be more challenging. Localized shaving and decalcification of the cusp can be performed, while leaving the cusp surface intact, to improve mobility. When this is not possible or in the setting of endocarditis, localized resection can be performed with the placement of patch material for cusp restoration. The presence of restrictive disease and the use of a patch have both been associated with reduced repair durability.^{13,32} In contrast, pericardial patch closure of fenestrations has been suggested to have acceptable outcomes.³³ The use of newer biomaterials is currently being explored and may help to overcome this limitation.³⁴

FIGURE 78-11 ■ Free margin resuspension technique using polytetrafluoroethylene (PTFE; Gore-Tex) suture for cusp prolapse correction.

Bicuspid Aortic Valve Repair

Bicuspid aortic valve disease affects not only the valve cusps, but also the functional aortic annulus. Bicuspid aortic valve can be divided into two general types^{13, 35} (Fig. 78-12). Type 0 bicuspid aortic valves do not contain a median raphe, have two symmetric aortic sinuses, two commissures, and a symmetric base of leaflet implantation of the two cusps. This configuration is present in a minority of cases. The mechanism of AI in this setting is usually cusp prolapse of one or both cusps because of the presence of excess cusp tissue.

Type 1 bicuspid aortic valves, which are significantly more prevalent, have a median raphe on the conjoint cusp and an asymmetric distribution of the aortic sinuses, with a large aortic sinus accompanying a large nonconjoint cusp and two smaller cusps fused together with a median raphe. The raphe often attaches to the cusp base in the form of a “pseudocommissure,” which has a height less

than that of the true commissures. The raphe may be restrictive, fibrotic, calcified, or prolapsing. Furthermore, the base of leaflet implantation is typically larger (i.e., occupying a greater proportion of valve circumference) and higher on the conjoint cusp compared to the nonconjoint cusp. The mechanisms of AI in type 1 valves can be due to a rigid and restrictive raphe associated with small fused cusps resulting in a triangular coaptation defect. Alternatively, the raphe may be short and nonrestrictive with well-developed cusps and associated prolapse of the conjoint cusp. Bicuspid valve anatomy can be anywhere along a spectrum between type 0 and type 1. The general algorithm for the repair of bicuspid aortic valves is presented in Figure 78-13.

In type 0 valves, the degree of prolapse is assessed by comparing the prolapsing cusp to the nonprolapsing cusp, similar to trileaflet valves. If both cusps are prolapsing, the goal is to restore the height of coaptation to the midpoint of the sinuses of Valsalva. This can be performed using free

FIGURE 78-12 ■ Cusp anatomy in bicuspid aortic valves.

FIGURE 78-13 ■ Algorithm for annulus and cusp management in bicuspid aortic valve repair.

margin plication, free margin resuspension with 7-0 PTFE suture, or both as previously described for trileaflet valves. Thickened, fibrotic areas of the leaflet (typically central aspect of the free margin) are shaved, and localized decalcification is performed if calcium is present.

In type I valves, the median raphe is addressed first. If the raphe is relatively mobile and only mildly thickened and fibrosed, it is preserved and shaved using a combination of a scalpel and scissors (Fig. 78-14). When a severely restrictive or calcified raphe is present, a parsimonious triangular resection of this tissue is performed (Fig. 78-15). Next, the quantity of remaining cusp tissue is assessed by putting the two arms of a 6-0 polypropylene suture on the free margin of the conjoint cusp, on either side of the resected raphe. At this point, lack of cusp

restriction and good valve opening are signs of the presence of adequate cusp tissue. The leaflet edges are reapproximated primarily when adequate cusp tissue is present using running locked or interrupted 6-0 polypropylene sutures. In the absence of adequate tissue, a triangular autologous treated or bovine pericardial patch is used for cusp restoration (Fig. 78-16).

Next, the free margins of both cusps are compared for the presence of any prolapse, which is corrected using free margin plication or resuspension with PTFE.

Unicuspid and Quadricuspid Aortic Valves

Unicuspid and quadricuspid are rare variants of aortic valve anatomy, and both can manifest with either valve

FIGURE 78-14 ■ Shaving of a noncalcified, fibrous raphe.

FIGURE 78-15 ■ Resection of a restrictive or calcified raphe (*top*) and assessment of the quantity of available tissue (*bottom*).

stenosis or insufficiency. The most common approach to the repair of the regurgitant unicuspid valve involves bicuspidization by creating a neocommissure using a pericardial patch. Techniques using a single or double patch have been described.^{32,36} These repairs are typically performed in the pediatric or young adult population, and long-term data on valve durability are lacking.

Quadracuspid aortic valves can have a variety of different orientations and may also be associated with aortopathy. Typically, one of the cusps has an additional attachment to the aortic wall and a raphe-like structure that causes cusp restriction. Repair is typically achieved by tricuspoidizing the valve by taking down this attachment and raphe and by repairing the affected cusp. Small

case series using this technique have shown good early results, but long-term data are lacking.^{15,37,38}

INTRAOPERATIVE ECHOCARDIOGRAPHY

In addition to providing important information regarding valve anatomy and mechanism of valve dysfunction, postrepair transesophageal echocardiography is mandatory in patients undergoing aortic valve repair.³⁹ More than trivial to mild residual aortic insufficiency (particularly eccentric jets), coaptation height below the aortic annulus, and coaptation length less than 5 mm have been shown to be important predictors of late repair failure and warrant aortic valve reexploration.⁴⁰

FIGURE 78-16 ■ Primary reapproximation (*top*) or use of pericardial patch for cusp restoration (*bottom*).

OUTCOMES

There are no randomized controlled trials comparing the outcomes of aortic valve repair versus replacement. Data on the durability of aortic valve repair techniques are currently limited to single-center series that are small to moderate in size, with a mean follow-up time of 5 to 10 years. However, data up to 18 to 20 years are emerging in certain subgroups. Important outcome variables include early mortality and morbidity, late freedom from reoperation and recurrent aortic valve insufficiency or stenosis, and the incidence of valve related complications of thromboembolism, bleeding, and endocarditis.

Overall

There are few studies reporting the outcome of unselected patients referred for aortic valve repair surgery. The success rate of valve preservation and repair in this context is rarely reported. Patients with aortic valve repair are typically a heterogeneous group representing the spectrum from young patients with congenital valve disease to older patients with degenerative aortic aneurysms and concomitant AI. As such, outcomes are frequently reported for specific subsets of patients undergoing aortic valve repair.

In a study examining the role of AI classification on surgical techniques and outcome, we evaluated 264 unselected patients undergoing aortic valve repair (mean

age, 54 ± 16 years; 80% male).¹¹ Approximately two thirds of patients were identified as having a single lesion causing AI. Two lesions were identified in 30% and three in 6% of patients. Fifty percent of lesions were type I (normal leaflet motion with FAA dilation or cusp perforation), 35% were type II (leaflet prolapse), and 15% were type III (leaflet restriction). The most common set of multiple lesions were prolapse of aortic valve leaflet in combination with type Ia (STJ dilation) or type Ib (aortic root aneurysm) disease. The classification of AI correctly predicted the surgical technique used in the vast majority of patients (82% to 100%). Overall survival in this cohort was $95\% \pm 3\%$ at 5 years and $87\% \pm 8\%$ at 8 years. Freedom from cardiac death was $95\% \pm 5\%$ at 8 years. Freedom from aortic valve reoperation and replacement at 8 years was $91\% \pm 5\%$ and $93\% \pm 4\%$, respectively. Importantly, classification of AI was also predictive of late outcome with patients with type III (restrictive cusp disease) demonstrating increased late aortic valve reoperation and recurrent AI (Fig. 78-17).

A recent meta-analysis examined the outcome of aortic valve preservation and repair in acute type A dissection and found good valve durability, low risk of valve-related complications, but a significant attrition of patients over time (4.7% per year).⁴¹

Valve-Sparing Aortic Replacement

Outcomes following valve-sparing aortic root replacement have been reported by a number of groups. Results

from large cohorts of patients performed in centers with experience with this technique generally show similar outcomes. David and colleagues⁴² were pioneers of the reimplantation technique and reported their experience in 289 patients, 228 of which underwent the reimplantation technique and 61 underwent the remodeling technique.^{43,44} Early mortality was 1.7%, and 12-year survival was 83%. Late freedom from reoperation at 12 years was 90% with the remodeling technique and 97% with the reimplantation technique ($P = 0.09$). Freedom from recurrent AI at 12 years was 83% after remodeling and 91% after reimplantation ($P = 0.035$). The authors concluded that the reimplantation technique provides more durable outcome.

Schafers and colleagues reported the outcome of the remodeling approach in 274 patients and found that early mortality was 3.6%, freedom from reoperation was 96% at 10 years and freedom from recurrent AI was 87% at 10 years.⁴⁵

Our group has reported outcomes in 164 consecutive patients who underwent valve-sparing aortic root replacement (74% reimplantation, 26% remodeling) specifically examining the effect of presence of preoperative aortic insufficiency on late outcome.⁴⁶ Severe preoperative AI was present in 57% of patients. In this cohort, early mortality was 0.6% and late survival was 88% at 8 years. Freedom from reoperation was 90% at 8 years, and freedom from recurrent AI was 90% at 5 years; both were independent of preoperative AI severity.

FIGURE 78-17 ■ Survival (A) and freedom (B) from aortic valve (AV) reoperation or replacement in an unselected cohort of patients undergoing aortic valve repair. C, Recurrence of aortic insufficiency (AI) according to lesion type shows increased AI recurrence in patients with type III disease.

Bicuspid Aortic Valve Repair

Unlike the results of valve-sparing aortic root replacement, results of bicuspid aortic valve repair reported in the literature have been highly variable between groups. These differences are largely due to the heterogeneity in the surgical techniques used, particularly the degree of annular stabilization. Schafers and colleagues⁴⁷ performed bicuspid aortic valve repair in 174 patients and found that freedom from reoperation was 97% at 5 years in those undergoing the remodeling approach but only 53% in those not undergoing root replacement.⁴⁷ A more recent update of their experience in 316 patients showed a 10-year survival of 92% and a 10-year freedom from reoperation of 81%. Absence of root replacement and a number of anatomic features of the bicuspid valve, including commissural orientation and VAJ diameter, were predictors of repair failure.¹² Alsoufi and colleagues⁴⁸ reported outcome following bicuspid aortic valve repair in 71 patients. Despite low early and late mortality, freedom from reoperation and recurrent AI at 8 years were 82% and 44%, respectively.

In our cohort of 122 patients undergoing bicuspid aortic valve repair (mean age, 44 years; 80% male, 57%

with associated aortic dilation), there was no early mortality and late survival was 97% at 8 years.¹³ Freedom from late aortic valve reoperation was 98% and 87% at 5 and 8 years, respectively, and freedom from recurrent AI was 94% at 5 years. In our experience, root replacement led to a more durable outcome compared with subcommissural annuloplasty alone (Fig. 78-18). A follow-up study was performed comparing patients undergoing valve-sparing root replacement using the reimplantation technique to all other forms of annular stabilization. Patients were matched for root and annular size and severity of preoperative AI. We found that patients undergoing the reimplantation technique had significantly lower rates of reoperation and recurrent AI.⁴⁹ This confirms the notion that the VAJ in patients with bicuspid aortic valve disease may continue to dilate over time and may cause repair failure.

Trileaflet Aortic Valve Repair

Different techniques can be used to correct cusp prolapse in trileaflet aortic valves. Free margin plication and free margin resuspension are the most commonly used techniques. Studies comparing the two techniques

FIGURE 78-18 ■ Survival (**A**) and freedom (**B**) from aortic valve (AV) reoperation or replacement, and (**C**) freedom from thromboembolism and bleeding in patients undergoing bicuspid aortic valve repair. **D**, Patients undergoing valve-sparing aortic root replacement had a higher freedom from recurrent aortic insufficiency than those undergoing subcommissural annuloplasty (SCA) with or without supracoronary ascending aortic (AA) replacement.

demonstrate equivalent durability in terms of freedom from reoperation or recurrent AI.^{31,50} Another important question in the repair of trileaflet aortic valves is the appropriate detection and localization of cusp prolapse. We examined echocardiographic and intraoperative features that could predict the need for cusp prolapse repair in trileaflet aortic valves with or without aortic root pathology. We found that the presence of a preoperative eccentric AI jet, regardless of severity, and the presence of a transverse fibrous band (see Fig. 78-4) were most useful in the detection and correct localization of cusp prolapse.¹⁷

Valve-Related Complications

A consistent finding across all longitudinal studies of aortic valve repair outcome is the low incidence of valve-related events. For prosthetic aortic valve replacements, the rate of thromboembolic events is typically between 1% and 2% per year.^{51,52} For patients with mechanical aortic valves, the rate of anticoagulant related hemorrhage is also 1% to 2% per year. Furthermore, valve thrombosis and prosthetic valve endocarditis are infrequent but devastating complications. In contrast, the combined rate of thromboembolism, bleeding events, and endocarditis following aortic valve repair has been reported in several studies to be less than 0.5% per year.^{11,13,53} This is particularly attractive for young patients who continue to accrue the risk of valve-related events over time.

CONCLUSION

Over the past two decades, important advances have been made in the field of aortic valve repair. These advances include a better understanding of the functional anatomy of the aortic valve, the development of a repair-oriented classification system for aortic insufficiency, the application of valve-sparing techniques to the preservation and repair of regurgitant aortic valves, and the development of cusp repair techniques. New data are available indicating the durability of aortic valve repair up to 10 years. Additional long-term studies and studies comparing aortic valve repair to replacement are needed to better define the role of aortic valve repair in patients with aortic insufficiency.

FUTURE DIRECTIONS

INTRODUCTION

Aortic stenosis is the most frequent acquired valve disease in older adult patients; consequently, the number of patients requiring treatment increases as the population ages. Current U.S. Census predictions indicate that by 2050 the number of citizens 85 years and older will reach 17.9 million and the number of citizens 65 years and older will reach 83.7 million.¹ Historically, aortic stenosis was treated with surgical aortic valve replacement (SAVR) using cardiopulmonary bypass via either a median sternotomy or minimally invasive techniques. These techniques have produced durable results with low morbidity and acceptable long-term survival rates.²⁻⁵ However, as the older adult population expands, more patients are developing aortic stenosis and multiple medical comorbidities that increase their operative risk. Despite several series demonstrating good clinical outcomes following SAVR in older adult patients,^{2,4,6} many physicians are reluctant to recommend surgery for high surgical risk patients with comorbidities. At least 30% of patients with severe symptomatic aortic stenosis are not treated with

SAVR because of reluctance by referring physicians, patients, or patients' families.⁶ In an attempt to mitigate risk in this frail, older adult population, transcatheter strategies for aortic valve replacement have been developed.⁷ In 2002, Cribier performed the first transcatheter aortic valve replacement (TAVR) through an antegrade approach using the femoral vein and a transseptal puncture technique due to advanced peripheral artery disease in an inoperable patient with severe aortic disease.⁸ In the subsequent decade, it is estimated that more than 60,000 TAVRs were performed worldwide.⁹ The techniques for TAVR have evolved and are currently being performed via retrograde transfemoral (TF), left ventricular transapical (TA), transcending aortic (TAo), transsubclavian (TS), and transcarotid (TC) approaches. This chapter focuses on the indications, preoperative evaluation, operative technique, outcomes, complications, and future of TAVR.

INDICATIONS

The classic indications for an isolated SAVR are symptomatic patients with severe aortic stenosis on transthoracic

echocardiography (TTE), defined as a peak aortic-jet velocity ($V_{\max}$) of at least 4.0 m/sec or mean aortic-valve gradient 40 mm Hg or higher.¹⁰ Typically the aortic valve area (AVA) is 1.0 cm² or less or an AVA index (AVAi) 0.6 cm² or less, but it can be larger secondary to mixed aortic stenosis/aortic regurgitation. The most common symptoms include exertional dyspnea or decreased exercise tolerance, angina, or syncope. In those with symptomatic but low-flow or low-gradient aortic stenosis with a reduced left ventricular ejection fraction, a dobutamine stress echocardiography can be used to ascertain the severity of the valve stenosis. In those patients who are asymptomatic, yet with very severe aortic stenosis ($V_{\max} \geq 5.0$ m/sec or mean aortic-valve gradient ≥ 60 mm Hg), valve replacement is recommended.¹⁰ Currently in the United States, TAVR is indicated in those patients with a life expectancy exceeding 1 year and severe aortic stenosis who are considered either high risk or inoperative by a multidisciplinary heart team, including those with expertise in cardiac surgery, invasive cardiology, echocardiography, cardiac anesthesia, and imaging specialties. Generally, high-risk patients are considered those defined by a Society of Thoracic Surgeons (STS) predicted risk score of mortality (PROM) of 8% or higher or by the presence of coexisting conditions that would be associated with a predicted risk of death by 30 days after surgery of at least 15%.¹¹ Outside the United States, the indications for TAVR are quite varied and are dependent on the institutional and geographic conditions.

PREOPERATIVE EVALUATION AND PLANNING

Patient selection is the key to successful TAVR. The methods of assessment of surgical risk vary but typically include the logistic EuroSCORE and/or the STS risk model. A logistic EuroSCORE higher than 20% and STS score higher than 8% expected mortality is generally accepted as high risk for surgery. Patients with limited life expectancy (<1 year), advanced chronic kidney disease (creatinine > 3.0), preoperative hemodialysis, advanced neurologic disease, and bicuspid aortic valves have been excluded from trials, and experience in these populations is limited but growing.

Pre-TAVR evaluation should seek to answer several questions, including (1) severity of aortic stenosis; (2) iliofemoral vessel size, calcification, and tortuosity; (3) anatomic details of the aortic valve leaflets; (4) annulus, sinotubular, and sinus of Valsalva dimensions; (5) ventricular viability; and (6) extent of coronary artery disease. A combination of imaging techniques may be used to answer these questions. At our institution, to discern these aspects a left heart catheterization, high-definition computed tomography (CT) of the chest, abdomen, and pelvis, and TTE or transesophageal echocardiography (TEE) are used to assess each patient prior to TAVR. Furthermore, objective frailty testing, pulmonary function tests, and carotid duplex ultrasound are performed to assess lung function and carotid stenosis. Severe, hemodynamically significant carotid lesions should be treated prior to TAVR.

Aortic Valve Assessment

A complete echocardiographic assessment is required to assess the aortic valve, most commonly using a TTE. From the parasternal long-axis view, the right and non-coronary cusps are identified, and the annulus is measured between the insertion points of the leaflets (Fig. 79-1). Accurate measurement is essential because this is what determines the size of the valve selected. If calcification, body habitus, or other factors preclude the accurate measurement of the annulus, a TEE ought to be performed. The right and noncoronary artery cusps are identified from the long-axis view at 120 degrees. Measurements of the sinus of Valsalva and sinotubular junction are also obtained from this view. The failure to properly size the annulus may result in a valve too small for the annulus with subsequent perivalvular leak or embolization, whereas a valve too big for the annulus may result in aortic dissection or annular damage. A TEE with three-dimensional reconstruction (Fig. 79-2) can be helpful in determining aortic annulus area and perimeter, which is

FIGURE 79-1 ■ Transthoracic echocardiogram. Parasternal long-axis view measuring the left ventricular outflow tract.

FIGURE 79-2 ■ Transesophageal echocardiogram with three-dimensional reconstruction measuring the aortic annulus area.

particularly useful in patients that were not able to get a three-dimensional CT reconstruction. Sizing of the annulus with supraaortic aortography during balloon aortic valvuloplasty (BAV) may provide additional information when the aortic annulus remains questionable.

All patients should have a CT scan from the aortic valve to the femoral arterial bifurcation. A gated, contrast CT will allow three-dimensional reconstruction, which will show in detail the aortic root anatomy, including the annular, sinotubular, and sinus of Valsalva dimensions, as well as coronary heights above the annulus (Fig. 79-3). Measurement of the annular area or perimeter have supplanted two-dimensional echocardiography in sizing for the appropriate TAVR device and are now the standard of care for assessment of implant size. Each vendor has a sizing chart corresponding to the annular area or perimeter. In those with chronic kidney disease, a three-dimensional TEE as aforementioned is performed to calculate the aortic annulus area and perimeter. This same CT will also delineate aortobifemoral anatomy, details of arterial vessel diameter, and tortuosity and calcification

FIGURE 79-3 ■ Cardiac contrast computed tomography with three-dimensional reconstruction measuring the aortic annulus area. **A-C**, Multiple views on computed tomography of the aortic annulus that are required for evaluation of the aortic valve for preoperative TAVR planning.

FIGURE 79-4 ■ Contrast computed tomography with three-dimensional reconstruction evaluating the aortoiliac/femoral anatomy. **A**, Anatomy adequate for most transfemoral TAVR valves. **B**, Anatomy not adequate for most transfemoral TAVR valves. **C**, Three-dimensional reconstruction of the iliac and femoral arteries.

(Fig. 79-4). In those with chronic kidney disease, a non-contrast CT and an invasive lower extremity angiogram provide complementary information, allowing for calibrated measurements of arterial diameters and easy detection of very focal stenosis and tortuosity.

Lower Extremity Assessment

Assessment of the lower extremities begins with either a CT scan or lower extremity angiography at the time of cardiac catheterization. Calcification of the large iliac arteries is common but generally does not prevent a femoral artery approach unless the calcification is circumferential and limiting in size. However, calcification in the smaller common femoral arteries is more problematic and may preclude the safe placement of TF systems and should be performed using alternative access techniques. Tortuosity, particularly in the external iliac artery, may complicate the advancement of the sheath. Consequently, moderate calcification in tortuous external iliac arteries (which tend to dive deep into the pelvis) may increase the likelihood of major vascular complications (Fig. 79-5). Tortuous vessels free of significant calcium are often compliant and can usually be straightened by a stiff guidewire. Figure 79-6 is a CT scan representation of severe iliac calcification precluding TF-TAVR.

Other Comorbidity Assessment

Patients with severe coronary artery disease and significant lesions that are amenable to percutaneous coronary intervention can undergo implantation of a bare-metal or drug-eluting stent prior to TAVR. Another potential concern is that the valve may displace a leaflet and cover a coronary ostium when deployed. A sinus of Valsalva that is narrow, a shallow sinus of Valsalva (within 5 mm of the annulus size), a short distance between the annulus and the coronary ostia (<10 mm), and bulky leaflet calcification can increase the risk for coronary obstruction. A sinus of Valsalva greater than 27 mm should accommodate smaller valves, whereas a sinus greater than 29 mm is adequate for all devices.

Alternative Access Considerations

Patients whose preoperative imaging study shows that a TF-TAVR is not advisable need to be evaluated for

FIGURE 79-5 ■ Contrast computed tomography with three-dimensional reconstruction with significant tortuosity of iliac vessels.

FIGURE 79-6 ■ Contrast computed tomography with three-dimensional reconstruction showing severe iliac-femoral calcifications.

alternative access techniques. A TA approach, via an anterior left mini-thoracotomy, has traditionally been used as the alternative in these patients. However, this approach comes with additional challenges and a different risk set compared with TF-TAVR and may not be appropriate for all patients, particularly those with significant parenchymal lung disease or low ejection fraction secondary to

FIGURE 79-7 ■ Contrast computed tomography with three-dimensional reconstruction to evaluate ascending aorta.

the direct cannulation of the left ventricle.¹² TAO is a feasible alternative approach for a TAVR in patients who have not had a previous sternotomy. It is important to evaluate the degree of ascending and aortic arch calcification and the distance from the cannulation (>7 cm) site and the aortic root to ensure adequate deployment of the valve (Fig. 79-7). The transcarotid approach has been used successfully in patients who are not candidates for TF, TA, or TAO.¹³

OPERATIVE TECHNIQUES

Transfemoral TAVR

The TF approach is the least invasive of all TAVR techniques and is the initial procedure of choice by most operators. A 6 Fr sheath is placed in the artery and vein on the nonimplant side. A pigtail catheter is advanced to the aortic valve and aortography is performed to confirm the correct valve plane for valve placement. Through the femoral vein, a temporary pacemaker is advanced to the right ventricular apex for purposes of rapid ventricular pacing. Maintaining consistent pacing capture is essential to safe TAVR. To gain stability and facilitate adequate contact of the pacemaker with the right ventricular myocardium, an 8 Fr Mullins sheath is advanced into the right atrium.

Alignment of the three cusps of the aortic valve is performed via ascending aortic root angiography. This can be performed with the angled pigtail catheter in the right coronary cusp or via power injection with the catheter in the aortic root. The proper aortic plane is identified when all three cusps are visualized at an equal height (Fig. 79-8).

Access to the femoral artery on the implant side is performed using a microneedle under vascular road mapping. The tract is dilated with a 7 Fr sheath and the artery is preclosed with two Perclose devices. Alternatively, a surgical cutdown to obtain femoral access can be performed to insert the sheath. The dilators are placed

FIGURE 79-8 ■ Aortic root angiogram. Alignment of all three coronary cusps. *L*, Left coronary cusp; *Non*, noncoronary cusp; *R*, right coronary cusp.

and the appropriate sheath is inserted. The patient is heparinized to an activated clotting time (ACT) of longer than 250 seconds. Excessive force should not be applied when passing the dilators to avoid vascular complications during insertion and removal. Next the aortic valve is crossed with an Amplatz left-1 (AL1) catheter. A straight-tipped guidewire or hydrophilic wire is used to cross the aortic valve and advanced into the ventricle. This is exchanged for a 260-cm long, 0.035-inch diameter Amplatz Extra Stiff J guidewire, which has an exaggerated pigtail bend at the proximal end. A BAV is performed under rapid ventricular pacing (generally 180 to 220 beats/min) using a Z-Med 20- or 23-mm balloon catheter.

The appropriate valve delivery system is inserted and advanced to the aortic annulus. Difficulty crossing the aortic valve can occur because the stiff wire can bias to the greater aortic curvature and become lodged in a commissure. Gentle pulling of the wire will allow the delivery system to centralize and cross the valve easier. Excessive force should not be used when crossing because dissection of the aorta can occur. Once the valve has crossed the native valve, the system should not be advanced further because perforation of the left ventricular apex by the nosecone is possible. The proper positioning of the valve is guided by fluoroscopy and echocardiography. The SAPIEN valve, a balloon-expandable valve, is ideally positioned so that its upper margin covers the aortic leaflet tips and the ventricular end covers the aortic annulus or below (Fig. 79-9). When the device is appropriately positioned, the implanting physician should coordinate a long cine-fluoroscopic run with rapid pacing and inflation/deflation of the delivery balloon. We advocate a slow inflation to ensure proper valve position. The balloon should be at maximal inflation for 4 seconds before deflation. It is important that pacing begins before balloon inflation and continues until the balloon is almost completely deflated. Successful rapid pacing with 1:1 ventricular capture at 180 to 220 beats/min lowers the

FIGURE 79-9 ■ Fluoroscopy of position of the SAPIEN valve in relation to the aortic annulus and coronary arteries.

FIGURE 79-10 ■ Fluoroscopy of position of the CoreValve in relation to the aortic annulus.

blood pressure below 60 mm Hg and prevents forceful contractions that may move the balloon catheter.

The CoreValve, a self-expanding aortic valve, is positioned by determining its three-tiered design in relationship with the aortic annulus. The inflow portion of the valve is ideally placed 6 mm (one diamond segment of the stent frame) below the point of leaflet attachment. Thus, the portion of the valve with high radial force sits firmly in the annulus, but not so low as to compress the adjacent cardiac conduction system (Fig. 79-10). The uppermost part of the CoreValve rests in the ascending aorta, parallel to the direction of blood flow. The CoreValve system does not commonly require rapid ventricular pacing during deployment.

Following deployment of the aortic valve, proper positioning is assessed with echocardiography. Patency of the coronary arteries is checked, and proper positioning of the device confirmed, with aortography. A valve too low in the ventricle may necessitate the placement of a second valve. Placing the valve too high in the annulus might result in embolization of the device into the ascending aorta or occlusion of the coronary arteries. A trace or mild amount of perivalvular leak is expected after TAVR. If there is more than mild leak around a correctly positioned valve, post-deployment balloon dilation using the balloon on the delivery catheter can further expand the valve and improve the insufficiency.

Transapical TAVR

The transapical TAVR is the second most common TAVR technique and thus far has been used primarily with a balloon-expandable valve. In those patients with severe peripheral vascular disease, the TA approach is an expeditious procedure. This technique is the only antegrade of all approaches with very low stroke rates and the least amount of postoperative paravalvular leaks. Furthermore, the TA procedure is best in those with a prior sternotomy or porcelain aorta. The most serious complication includes left ventricular bleeding, but this is not common. The only relative contraindications to the TA procedure are severe chronic obstructive pulmonary disease (COPD) with a forced expiratory volume (FEV₁) predicted less than 30% or an ejection fraction less than 20%.

The patient is placed supine on the operating room table and femoral artery and vein access is achieved. A femoral transvenous pacer is placed in the right ventricle and a pigtail catheter is placed in the aortic root via the femoral artery. A 4- to 5-cm anterolateral thoracotomy is made in the fifth or sixth intercostal space to expose the left ventricle. Two apical pledgeted 3-0 Prolene purse-string sutures are placed just cephalad to the apex lateral to the left anterior descending artery. The purse-string sutures into the myocardium should be deep stitches but not transmural (Fig. 79-11).

Fluoroscopy is used to position the aortic root and annulus perpendicular to each other, and to align all three aortic cusps in the same plane in a similar fashion as in the TF approach. The left ventricle cavity is accessed

FIGURE 79-11 ■ Transapical transcatheter aortic valve replacement approach. Left thoracotomy with exposure of the apex of the heart with two purse-string sutures.

with a needle, and a 0.035-inch wire is passed into the left ventricle, across the aortic valve, and into the ascending aorta. The wire is maintained in the ascending aorta and not allowed to pass into the right carotid artery. A 7 Fr catheter is placed through the left ventricle apex and across the aortic valve. The 0.035-inch wire is manipulated into the descending aorta using a right Judkins catheter. The 0.035-inch wire is exchanged for a stiff wire (Amplatz Super Stiff; Boston Scientific, Natick, MA) and left in the abdominal aorta. The 7 Fr catheter is exchanged for the appropriate sized delivery sheath, which is positioned 4 cm inside the left ventricle. A BAV is performed with or without rapid ventricular pacing. The balloon is removed and the valve is placed through the left ventricular delivery sheath and positioned across the valve. Positioning, deployment, and post-assessment of the valve are similar to that as aforementioned in the TF-TAVR section. After adequate evaluation, all catheters and wires are removed and the apex sutures are tied down under rapid ventricular pacing. Protamine is administered. If possible, the pericardium is closed over the left ventricular apex surgical site, and a small flexible chest tube is placed in the left pleural space.

Transaortic TAVR

The TAo approach is the third most common TAVR technique and is used in those with balloon- or self-expanding valves. The TAo approach has several theoretical and practical advantages, including avoiding a thoracotomy in patients with poor respiratory function, less postoperative pain, and faster recovery. In addition, the direct aortic cannulation, a procedure with which most cardiac surgeons are comfortable, potentially allows for a more hemostatic closure than in a patient with a fragile left ventricular apex. However, although the TAo approach offers several advantages, it is not appropriate for all patients. TAo-TAVR is contraindicated in patients with porcelain aorta. There are also additional technical challenges when considering the TAo approach in patients with previous sternotomies, prior left internal mammary artery (LIMA) grafts that overlay the aorta, or otherwise hostile mediastinum (e.g., patients with a history of cobalt radiation).

The patient is placed supine on the operating room table with the lower neck exposed to allow for the counter-incision for the delivery sheath. An angled pigtail catheter is placed in the aortic root and a femoral transvenous pacer is placed in the right ventricle. The CT can provide the adequate information of the relationship of the distal ascending aorta to the sternum, the extension of calcification, and the distance from the site of cannulation to the aortic root. This distance should be ideally greater than 7 cm to allow enough space between the delivery system and the free inflation of the balloon during the valve implantation (see Fig. 79-7).

A 5- to 6-cm sternotomy incision is made below the suprasternal notch extending below the angle of Louis at the second intercostal space. A mini-sternotomy is performed using a standard saw, dividing the sternum down to the second intercostal space, where the “J” is completed with a transverse sternotomy. The distal ascending

aorta is exposed and two aortic purse-string sutures are placed at the base of the innominate artery. The patient is heparinized to maintain an ACT greater than 250 seconds. A counter-incision is made in the lower neck through which an 18-gauge needle with a 0.035-inch soft guidewire is passed and used to puncture the aorta through the purse-string sutures (Fig. 79-12). The needle is exchanged for a 7 Fr sheath, and a multipurpose catheter with a straight soft wire is used to cross the valve. This is exchanged for a 260-cm, 0.035-inch Amplatz Extra Stiff J guidewire, which has an exaggerated pigtail bend at the proximal end. The appropriate sheath is placed into the aorta to 2 to 4 cm. A BAV is performed under rapid ventricular pacing. The balloon is removed and the TAVR valve is placed through the delivery sheath and positioned across the stenotic valve. Positioning, deployment, and post-assessment of the valve are similar to that as aforementioned in the TF-TAVR section. After adequate evaluation, all catheters and wires are removed and the aortic sutures are tied down under rapid ventricular pacing. Protamine is administered and generally the pericardium is left open. A small flexible chest tube is placed in the mediastinum and generally the pleural spaces are not opened.

Subclavian TAVR

The transsubclavian approach is the fourth most common TAVR technique and is used primarily in those with a self-expanding valve. Approaching TAVR from the axillary artery presents a few distinct advantages when compared with the other alternative access routes. It remains less invasive compared with the TA or TAO approach because it does not require thoracotomy or limited sternotomy. This makes it appealing for the older, debilitated patient in whom the transfemoral approach is limited by anatomy. Furthermore, in cases of aortic calcification, which would limit the TAO approach, or severe left ventricular or pulmonary dysfunction, which would limit the TA approach, the axillary access route is potentially preferable.

FIGURE 79-12 ■ Transaortic transcatheter aortic valve replacement approach.

Standard femoral artery and vein access is obtained as aforementioned. Surgical cutdown for the left axillary artery is familiar to most cardiac surgeons because it is routinely used as an arterial inflow cannulation site, particularly in the setting of aortic surgery. An oblique incision is made in the deltopectoral groove. The first portion of the axillary artery can be exposed with lateral retraction of the pectoralis minor. Division of the head of pectoralis minor can be performed with minimal morbidity if necessary to obtain optimum exposure. Great care is taken to avoid injury to the medial and lateral cords of the brachial plexus, as they often travel in close association with the artery, particularly in its second portion. The patient is heparinized to maintain an ACT greater than 250 seconds. Use of a synthetic graft in an end-to-side orientation, which is then cannulated with the delivery sheath, is favored by some, whereas others use direct access via a purse-string suture. Using the Seldinger technique, the access site is dilated to accommodate the appropriate caliber delivery sheath for the chosen device. This is advanced over a stiff wire, using fluoroscopic guidance with the tip of the sheath left at the origin of the innominate artery when approached from the left. When approaching from the right, the concern for potential occlusion of the right common carotid artery has led some high-volume centers to position the sheath tip at the origin of the right subclavian artery. Once the sheath is appropriately placed, TAVR deployment proceeds using the usual protocol of the transaortic TAVR. At the conclusion of the procedure, following removal of the delivery sheath, vascular control of the access site is obtained and selective angiography can be used to confirm vessel integrity at the access site.

Transcarotid TAVR

For patients who are not candidates for TF-, TA-, or TAO-TAVR and who have a common carotid artery diameter larger than 8 mm without evidence of stenosis, the TC approach to TAVR can be used.¹³ A 6 Fr sheath is placed in the femoral artery through which an angled pigtail catheter is used for ascending aortography. In the contralateral femoral artery, a 16 Fr Fem-Flex II cannula (Edwards Lifesciences, Irvine, CA) is placed percutaneously. This cannula is connected to perfusion tubing and a 14/15 Sundt carotid bypass shunt (Covidien, Mansfield, MA) (Fig. 79-13). A pacing catheter is placed via the femoral vein. The right common carotid artery is exposed

FIGURE 79-13 ■ Transcarotid transcatheter aortic valve replacement approach with visualization of the femoral-carotid shunt.

and after proximal cross-clamping of the common carotid artery, it is opened longitudinally for 2.5 cm. The de-aired bypass shunt is placed in the distal carotid arteriotomy to maintain cerebral perfusion. Cerebral oximetry from the left and right hemispheres is monitored throughout the procedure. Through the proximal arteriotomy, a 0.035-inch J-tipped wire and 7 Fr introducer are placed in the ascending aorta. A multipurpose catheter is then inserted into the ascending aorta and a straight wire is used to cross the native aortic valve. The straight wire is exchanged for an Amplatz Extra Stiff wire, and a Retroflex sheath is introduced into the ascending aorta. Similar to the transfemoral TAVR, a BAV followed by the placement of a valve is performed. Finally, the wires, catheters, and sheath are removed, and the carotid artery is repaired with a bovine pericardial patch.

RESULTS

SAPIEN Valve

The Placement of Aortic Transcatheter Valves (PARTNER) trial was a landmark and the first randomized study that demonstrated the superiority of TAVR over medical therapy in inoperable patients^{11,14} and the noninferiority of TAVR versus SAVR in high-risk surgical candidates using the balloon-expandable SAPIEN valve.^{15,16} Based on the 1-year outcomes from PARTNER, the SAPIEN valve was approved by the U.S. Food and Drug Administration for use in patients who are not candidates or are at high risk for SAVR.

The results of the randomized, multicenter U.S. PARTNER trial in patients too high-risk for surgery have been published by Leon and colleagues. In this report of 179 patients, the procedural success rate was 96.6%. The AVA and mean gradients across the aortic valve were significantly improved to 1.5 ± 0.5 cm² and 11.1 ± 6.9 mm Hg at 1-year follow-up (preprocedure AVA 0.6 ± 0.2 cm² and mean gradient 44.5 ± 15.7 mm Hg; $P < 0.001$). Mortality was 5.0% and 30.7% at 30 days and 1 year, respectively, following TAVR, establishing its superiority to medical therapy (1-year mortality 49.7%; $P < 0.001$).¹¹

An evaluation of the STS adult cardiac surgery database notes that approximately 6% to 7% of patients presenting for surgical AVR in North America are considered at high risk with an STS score of 8% or higher.^{3,4} At a minimum, this represents a large number of patients who now will have an option for TAVR or SAVR. It is estimated that approximately 30% to 38% of high-risk, older adult patients are not receiving SAVR despite echocardiographic evidence of severe aortic stenosis.^{6,17} The PARTNER trial represents the first randomized trial comparing TAVR with SAVR in high-risk patients. Many physicians have noted that the results may be skewed secondary to the surgical procedure being performed in select university settings. In a multi-institutional study, 159 patients undergoing isolated, primary SAVR with an average STS PROM of $16\% \pm 7\%$ had a 3-year survival of 57% and a median survival of 3.7 years.¹⁸ In a real-world analysis of the STS database, Brennan and coworkers noted a median survival of 2.5 to 2.7 years in high-risk

patients (STS $\geq 10\%$) undergoing SAVR.⁴ Similarly, the SAVR group in the current series has a 55.8% survival at 3 years and a median survival of 3.4 years.

A report by Thourani and colleagues represents the largest series and the first long-term analysis using fully adjudicated outcomes in randomized high-risk patients with aortic stenosis undergoing TAVR with a balloon-expandable valve or surgery (PARTNER trial).¹⁹ At a minimum of 3 years, there was no difference in all-cause and cardiovascular mortality rates between the TAVR and SAVR groups (Fig. 79-14). Strokes were similar between the groups at 3 years, despite increased periprocedural neurologic events in TAVR patients. There was no late (after 30 days) stroke hazard in TAVR compared with SAVR. At 3 years, TAVR hemodynamic performance was maintained with valve gradients and AVAs similar to those of SAVR (Fig. 79-15). In both groups,

Numbers at risk						
TAVR	298	262	243	228	210	188
AVR	351	236	224	209	191	168

FIGURE 79-14 ■ PARTNER trial 3-year analysis: all-cause mortality. AVR, Aortic valve replacement; CI, confidence interval; HR, hazard ratio; TAVR, transcatheter aortic valve replacement.

FIGURE 79-15 ■ PARTNER trial 3-year analysis: hemodynamic valve performance by echocardiography. AVR, Aortic valve replacement; TAVR, transcatheter aortic valve replacement.

FIGURE 79-16 ■ PARTNER trial 3-year analysis: impact of aortic regurgitation (AR) on mortality. TAVR, Transcatheter aortic valve replacement.

structural valve deterioration was not apparent at the 3-year follow-up. Postprocedural paravalvular aortic regurgitation was frequent after TAVR without important changes during the 3-year follow-up (Fig. 79-16). Of note, and as has been previously reported, even mild postprocedural aortic regurgitation (paravalvular leak [PVL] and total aortic regurgitation) was associated with increased subsequent mortality.¹⁶

Other reports have noted the mid- and long-term TAVR survival rates in Gurvitch and colleagues' study of 70 patients (mean STS score 9.6% and EuroSCORE 31.7%) who underwent successful TAVR with a balloon-expandable valve and who survived 30 days and were followed for a minimum of 3 years.²⁰ The authors noted a survival at 2 and 3 years of 74% and 61%, respectively.²⁰ Correspondingly, the PARTNER series of 348 TAVR patients (mean STS PROM 11.8%) had a 66.5% survival at 2 years and 56.4% survival at 3 years. Similar to the PARTNER series, Gurvitch and colleagues noted no cases of structural valvular deterioration, and only one patient (1.5%) in their series underwent reoperation secondary to endocarditis. In a retrospective, single-center European analysis, Bleiziffer and colleagues reviewed outcomes in 227 patients undergoing TAVR with both balloon-expandable and self-expanding valves for at least 2 years follow-up. In their series, the mean STS PROM was 7% and EuroSCORE 21%, possibly representing a lower risk patient population. They noted a 2-year survival of 66.4%.²¹ In the multicenter UK TAVI Registry of 870 patients undergoing balloon-expandable and self-expanding valve implantation, Moat and colleagues noted a 73.7% all-cause survival at 2 years.²² This figure compares favorably to the 66.5% survival at 2 years in the PARTNER series. However, the UK registry data may not represent a high-risk patient population, with only an average logistic EuroSCORE of 18%.

CoreValve

An early, pioneering series from Grube and colleagues established the self-expanding CoreValve as a viable treatment option for severe aortic stenosis in patients at high risk for morbidity or mortality related to operative intervention (SAVR). Of 25 consecutive patients receiving the CoreValve, 21 (84%) patients were designated procedural successes, and there was a 20% overall mortality.²³ With progressive refinements in technique and device iterations, procedural success improved and the 30-day mortality decreased to 12%. Based on the positive results of these studies and others,^{24,25} CE mark designation for the self-expanding valve was obtained in April 2007.

In the year following obtaining CE mark, 646 patients treated with CoreValve were followed in a multicenter registry. Procedural success was achieved in 97% of patients with a procedural mortality of 1.5%. The incidence of vascular access complications was 1.9% and the 30-day mortality was 8%. A total of 60 patients (9.3%) required placement of a permanent pacemaker. Approximately 70% of the patients had residual aortic insufficiency of grade 1 or 2.²⁶

The introduction of CoreValve to the United States began with a multicenter randomized trial that began in late 2010. The Medtronic CoreValve U.S. pivotal trial adopted a similar trial design to that of the PARTNER trial by targeting aortic stenosis patients at high risk or extreme risk for traditional SAVR. The extreme risk group did not require randomization because the previous findings from the PARTNER study demonstrated a clear survival benefit for TAVR compared with medical therapy. Popma and colleagues reported on 489 patients with a mean STS risk score of 10.3% and mean age of 83 years. The noted all-cause death was 8.4% at 30 days and 24.3% at 1 year. Major stroke was noted at 2.3% at 30 days and 4.3% at 1 year. Major or life-threatening bleeding was noted in 36.7% and the need for permanent pacemaker was 21.6%. The percentage of patients with moderate or severe PVL at discharge was 10.5%. Interestingly, the investigators noted that the severity of PVL diminished over time. In fact, 80% of the patients who had moderate PVL 1 month and survived to 1 year had a reduction in PVL severity.²⁷

In a follow-up study, Adams and associates reported on 795 high-risk patients randomized to either SAVR or TAVR with severe aortic stenosis.²⁸ The mean STS risk score was approximately 7.4% and represented a less sick group than the PARTNER high-risk study, which had a mean STS score of 11.8%.¹⁵ The primary endpoint of all-cause mortality at 1 year illustrated a statistically significant difference between the two groups. Patients undergoing TAVR had a lower all-cause mortality at 1 year (14.2% vs. 19.1%; $P = 0.04$). Permanent pacemaker implantation was higher for CoreValve recipients at 30 days (19.8% vs. 7.1%; $P < 0.001$) and again at 1 year (22.3% vs. 11.3%; $P < 0.001$). Once again, investigators noticed an improvement in paravalvular regurgitation over time. In fact, most of the patients with moderate or severe paravalvular regurgitation at discharge had improved by 1 year to mild or better. Overall the study

represents the first prospectively randomized comparison demonstrating improved survival at 1 year for TAVR compared with SAVR.

The early challenges related to pacemaker implants and PVL have been demonstrated by others. The UK TAVI Registry reported prospectively collected data on TAVR patients implanted up until December 2009.²² Of the 452 CoreValve implants included in the study, 17.3% had moderate to severe aortic insufficiency compared with 9.6% of SAPIEN implants ($P = 0.001$). Furthermore, 24.4% required permanent pacemaker implantation compared with 7.4% of SAPIEN implants ($P < 0.001$). Procedural success was still excellent (98.2%) and 30-day mortality remained acceptable at 5.8%. In the only randomized trial comparing the transfemoral balloon-expandable (SAPIEN XT) and self-expanding (CoreValve) valves, Abdel-Wahab and colleagues randomized 240 patients to receive one of the two valves.²⁹ They noted a significantly lower frequency of residual aortic regurgitation based on intraoperative angiography (41% vs. 18%; $P < 0.001$) and less frequent need for implanting more than one valve in the SAPIEN patients. Cardiovascular and overall mortality at 30 days was similar in both groups. They also noted that the need for a permanent pacemaker was significantly lower in the SAPIEN valve group (17% vs. 38%; $P = 0.001$).

In general, when compared with SAVR, TAVR has been shown in high-risk surgical patient populations to have similar mid-term mortality.^{15,16,19,30,31} An important observation of the aforementioned studies is that despite the relief of aortic stenosis, this high-risk patient cohort continues to have a progressive mortality rate reaching approximately 40% to 45% at 3 years. Although this may be secondary to the inherent comorbidities and age of this patient population, it remains incumbent for health care providers to redefine the most appropriate patients for any therapy or TAVR or SAVR.

TAVR in Patients with Prior SAVR

Tissue prostheses carry a low risk of thromboembolic events (between 0.5% and 1% risk per year without anticoagulation) but have a higher chance of valvular degeneration, requiring the potential need of a repeat surgical intervention at 10 to 15 years from implantation.

Fundamental types of information to determine are the valve type, valve size, and technical technique used in the primary valve surgery. There are numerous types of bioprostheses valves implanted in the aortic position. This could be xenografts (most frequently obtained from bovine pericardial or the porcine aortic valve or root) or homografts. Bioprostheses can also be divided into stented and stentless valves. For each surgical valve to be treated, it requires understanding of the structural and fluoroscopic characteristics for an accurate positioning of the valve in valve (V-in-V). When planning for the adequate sizing for the V-in-V, the important measurement is the true inner diameter of the valve. Other relevant measures include post and leaflet heights, the position of the valves within the aortic root and the relationship with the coronary ostia, and the presence of coronary bypasses.³²

The complications resulting from TAVR in patients with prior SAVR differ from those of standard TAVR. Because the V-in-V is deployed in a fixed structure, it is less frequent to have annular rupture, bleeding complications, paravalvular regurgitation, and new events of conduction abnormalities. There is, however, an increased incidence of valve malpositioning (especially in previous aortic root replacement or stentless valves secondary to the absence of fluoroscopic markers), coronary obstruction (mainly secondary to the displaced leaflets of the failing prosthesis against the coronary ostia), and increase of postoperative aortic prosthesis gradients secondary to underexpansion of the transcatheter valve in a nonexpandable failing prosthesis ring.³³

SPECIFIC PATIENT COMORBIDITIES

With increasing awareness of less invasive techniques available for the treatment of high-risk patients with severe aortic stenosis, there remains controversy over the appropriate therapy regarding SAVR or TAVR. Although this decision may be difficult when based solely on the STS predicted risk of mortality, a more realistic decision-making tool includes the identification of specific patient subgroups that may benefit preferentially from TAVR or SAVR.

Gender

To date, there remains a paucity of studies investigating the impact of gender-related differences following TAVR or SAVR.³⁴⁻³⁷ In an analysis of patients from the PARTNER trial by Williams and coworkers, there was reduced procedural mortality in females undergoing TAVR compared with SAVR (6.8% vs. 13.1%; $P = 0.07$).³⁵ At 2 years, all-cause mortality was significantly lower in females undergoing TAVR (28.2% vs. 38.2%; $P = 0.049$). These investigators also noted that the differences in the reduced late mortality were predominantly in the transfemoral cohort (23.4% vs. 36.9%; $P = 0.02$), whereas there was a less striking benefit in the transapical cohort (37.3% vs. 41.7%; $P = 0.62$). Although procedural mortality also favored TAVR over SAVR in males (6.0% vs. 12.1%; $P = 0.03$), there was no benefit in all-cause mortality at 2 years in the TAVR group (37.7% vs. 32.3%; $P = 0.42$). Moreover, there was no reduction in 2-year mortality in either the transfemoral ($P = 0.86$) or the transapical arms ($P = 0.21$) in males.³⁵ It is plausible that these results suggest that TAVR and, when feasible, the transfemoral route might be the preferred treatment option for older women with symptomatic severe aortic stenosis.

Diabetes Mellitus

Another high-risk patient population presenting with severe aortic stenosis are those with preoperative diabetes mellitus. In 1391 patients undergoing isolated SAVR, Halkos and his colleagues at Emory reported significantly reduced 10-year survival in patients with diabetes (40.5%) compared with those without diabetes (71.2%; $P <$

0.001).³⁸ Only one report thus far has compared outcomes in high-risk diabetic patients undergoing TAVR ($n = 145$) and SAVR ($n = 130$). From a post hoc analysis of the PARTNER trial, Lindman and colleagues noted all-cause mortality at 1 year was 18.0% in TAVR patients and 27.4% in the surgical group ($P = 0.04$).³⁹ In contrast, there was no significant difference in 1-year mortality in nondiabetic patients between groups ($P = 0.48$). These data suggest that TAVR may be the preferred treatment approach for patients with aortic stenosis and diabetes who are at high risk for surgery.

Mitral Regurgitation

The presence of moderate or severe mitral regurgitation (MR) with concomitant aortic stenosis represents a difficult and common patient population. Following isolated SAVR,⁴⁰ but not TAVR,^{41,42} preoperative moderate or severe MR has been associated with worse early and late survival. In a post hoc analysis of the PARTNER trial comparing SAVR and TAVR in those with concomitant MR, Barbanti and coworkers showed that similar changes in left ventricular remodeling and improvement in left ventricular function occur following relief of the aortic stenosis by either SAVR or TAVR.⁴² Correspondingly, improvements in symptoms and functional class were found with both procedures, regardless of the severity of MR. However, in those undergoing SAVR, all-cause mortality at 2 years was higher in those with preoperative moderate or severe MR compared with those with mild or less MR (49.8% vs. 28.1%; $P = 0.04$). In contrast, MR severity at baseline did not affect mortality in TAVR patients (37.0% vs. 32.7%; $P = 0.58$). Unfortunately, current studies have not differentiated the impact of TAVR route (i.e., TF, TA, TAO) on long-term outcomes in this patient population. In select high-risk patients with nondegenerative moderate to severe MR and concomitant severe aortic stenosis, it may be reasonable to consider TAVR as a less invasive mode of therapy.

Renal Dysfunction

A strong association exists between aortic stenosis and renal dysfunction with up to 75% of patients having mild, moderate, or severe renal dysfunction.⁴³ We and others have shown that preoperatively impaired renal function represents a strong independent predictor of adverse short- and long-term outcomes in SAVR and TAVR patients.^{43,44} Recently, Nguyen and colleagues from Emory University compared renal dysfunction within SAVR ($n = 1336$) and TAVR ($n = 343$) patients. They noted an in-hospital mortality in TAVR patients for mild, moderate, and severe renal dysfunction of 3.8%, 2.9%, and 4.4% ($P = 0.89$), respectively. On the contrary, in the SAVR group, worsening renal function was associated with a stepwise increase in short-term mortality, at 2.6%, 4.1%, and 8.9% for mild, moderate, and severe renal dysfunction, respectively. Furthermore, worsening renal function was strongly associated with increased mid- and long-term mortality in the SAVR group, whereas Kaplan-Meier survival estimates for TAVR stratified by renal function do not demonstrate this relationship. In all

patients, the adjusted odds ratio for death was 0.47 when comparing TAVR with SAVR.⁴⁵ In SAVR patients, the adjusted odds ratio for death was 2.6 when comparing severe/dialysis with normal patients. In TAVR patients, the odds ratio was 1.01 when comparing severe/dialysis with normal patients. Although more research and analysis is needed to elucidate the preferential benefit of TAVR in patients with renal dysfunction, it is possible that TAVR mitigates the effect of moderate and severe renal dysfunction on short- and mid-term survival.

COMPLICATIONS

Although TAVR was designed to be a less invasive form of aortic valve replacement for high-risk patients, it still carries many of the same potential complications for open, traditional aortic valve replacement. The Valve Academic Research Consortium-2 (VARC-2) has standardized the endpoint definitions for studies evaluating the use of TAVR, which will lead to improved comparability and interpretability of the study results.⁴⁶ Denoted in this section are the most common complications associated with TAVR.

Acute Hypotension

Acute hypotension during TAVR is not uncommon and may be due to acute aortic insufficiency, left ventricular dysfunction (caused by “stunning” with rapid pacing, ostial coronary occlusion, or other factors), pericardial effusion (typically from right ventricular perforation by the pacing wire or aortic root trauma), arrhythmia, peripheral vascular injury, a “suicide ventricle” (hyperdynamic intraventricular obstruction after unloading by BAV or TAVR), or other factors. Treatment of acute hypotension is dictated by its causes. In the absence of an anesthesiologist, operator-administered boluses of intra-aortic, intraventricular, or intravenous epinephrine or norepinephrine are immediately deliverable and effective temporizing measures. The suicide ventricle, although uncommon, is suggested by high residual gradients, especially dynamic obstruction (worse after a premature beat); can be identified echocardiographically; and is important to differentiate from other causes of acute heart failure: it will be aggravated by diuresis and positive inotropes but can be effectively treated with volume, vasoconstrictors, and negative inotropes.

Stroke

In addition to mortality, one of the most devastating consequences following aortic valve replacement is a new postoperative permanent stroke. Following SAVR in high-risk surgical patients, stroke rates have been reported between 3% and 5%.^{4,5,15,18} The incidence of cerebrovascular events (transient ischemic event or a stroke) during the 30-day period after TAVR ranges from 3% to 7%.⁴⁷ Approximately 50% to 70% of these events occur during, or within 24 hours of, the procedure. In the PARTNER study, an analysis of 30-day and 1-year outcomes, there was an increased periprocedural stroke following TAVR

when compared with SAVR.^{15,48} However, at 2 years and in a more recent study of the PARTNER patients by Thourani and coworkers, there does not appear to be any evidence of a continued increased stroke at the 2- and 3-year follow-up in TAVR patients.^{16,19} In an analysis of the PARTNER trial by Dewey and colleagues, the authors noted improvement in the periprocedural stroke rate from 6.7% in the premarket approval TA-TAVR ($N = 104$) when compared with 2.2% in the nonrandomized continued access TA-TAVR group ($N = 975$).⁴⁹ In a recent meta-analysis, Eggebrecht and associates have shown an overall 30-day stroke/TIA rate was $3.3 \pm 1.8\%$ with most being major strokes ($2.9 \pm 1.8\%$).⁵⁰

Stroke in association with TAVR can occur because of atheroembolism, thromboembolism, cardiogenic shock during the procedure, preexisting cerebral vascular disease, or interaction of these factors. However, catheter manipulation in the ascending aorta is the most likely cause of most strokes observed with TAVR. Predictors of neurologic events were balloon post dilation, valve embolization, and new onset of atrial fibrillation.⁵¹ Major, ischemic stroke may be treated by catheter-based, mechanical embolic retrieval where available. Thrombolysis may also be considered, although the expected benefit may be reduced (particularly with atheroembolism); bleeding risk is typically high because of patient age and morbidity as well as the arteriotomies created for TAVR (if recent). Clinical studies evaluating the most appropriate anticoagulation regimen are also forthcoming.

One of the most recent aspects of stroke prevention includes new cerebroembolic protection devices, which are actively being evaluated and have shown promise in the reduction of embolic debris during TAVR.⁵²⁻⁵⁴ These devices can be categorized in two broad categories: (1) deflectors, which prevent passage of emboli to the cerebrovascular system by redirecting them to the lower half of the body, and (2) retrieval devices, which capture and collect emboli for removal from the systemic circulation.

Among the deflector devices, the Embrella Embolic Deflector (Edwards Lifesciences) and the Triguard (Keystone Heart, Ltd.) have the largest clinical experience to date (Fig. 79-17). Both devices use a nitinol frame that is positioned across the origin of the great vessels in the aortic arch. The Embrella device uses a polyurethane membrane with pore size of $100 \mu\text{m}$ to selectively deflect emboli. The Triguard is a nitinol mesh with a pore size

FIGURE 79-17 ■ Embrella Embolic Deflector (Edwards Lifesciences).

of $140 \mu\text{m}$. The Embrella uses a right radial or brachial approach for deployment, whereas the Triguard is delivered via the femoral artery and covers the entire arch, including the left subclavian artery.

The retrieval system with the most clinical experience to date is the Montage Dual Filter (Claret Medical, Inc.) (Fig. 79-18). The system uses right upper extremity access to place two conical filters with $140\text{-}\mu\text{m}$ polyurethane membranes in the brachiocephalic and left common carotid arteries. At the completion of the procedure, the filters are withdrawn and captured debris is removed from the circulation. A first-in-human series was reported in 2012 detailing use in 40 patients. The series included two generations of the device with improvements in proper placement for the second generation (87%) compared with the first generation device (60%).⁵³ Macroscopic debris was removed from 19 (54%) patients treated; one minor stroke (at 30 days) and two major strokes (at 4 hours, at 27 days) were observed.

Acute Kidney Disease

Significant acute kidney injury (AKI) after TAVR has been reported to be 8%, being an independent predictor of mortality.⁵⁵ The origin of AKI is likely to be multifactorial, involving predisposing conditions such as diabetes mellitus, chronic kidney disease, or peripheral vascular disease, and procedure-related events such as aortic plaque embolism in the renal arteries and hypoperfusion during rapid ventricular pacing. The use of the TA approach has been reported to be an independent predictor of AKI in several studies, probably reflecting underlying comorbidities that predispose these patients to such a complication.

Vascular Complications

Vascular injury at the access site is the most frequent problem with transfemoral TAVR. Major vascular complications occurred in 15% of patients within 30 days of TF-TAVR in the PARTNER trial and were associated

FIGURE 79-18 ■ Montage Dual Filter (Claret Medical, Inc.).

with significantly higher rates of 30-day and 1-year mortality.¹¹ Vascular access site complications are mainly related to the large caliber sheaths used to deliver the valve. The first generation of sheaths (22 to 25 Fr, corresponding to an outer diameter of 9 to 10 mm) was associated with high rates of vascular complications. However, with growing operator experience, improved patient screening and selection, and the smaller diameter of the newer generation of sheaths (18 or 19 Fr, corresponding to an outer diameter of 7.2 to 7.5 mm), the incidence of vascular complication has significantly decreased over time. Within the next few years, we would expect vascular injuries to be below 5%.

Other major vascular complications include thoracic aortic dissection; rupture of the aortic annulus; distal embolization (noncerebral) from a vascular source, requiring surgery or resulting in amputation or irreversible end-organ damage; access-site or access-related injury leading to death, the need for blood transfusion (>4 units), unplanned percutaneous or surgical intervention, or irreversible end-organ damage.⁴⁶

Aortoiliac avulsion or perforation may be suspected during arterial dilation and insertion of the delivery sheath, but it may not be clinically manifest until removal of the delivery sheath. If perforation is identified at sheath removal, the sheath should be immediately reinserted (with dilator in place) to help tamponade the bleeding while preparation for more definitive treatment is made. Depending on the site and severity of injury, an aortic occlusion balloon such as the Coda balloon (Cook Medical, Bloomington, Illinois) may be inserted from the contralateral arterial access site. Prolonged balloon tamponade using peripheral angioplasty balloons may be helpful for iliac or femoral perforation, and deployment of covered stents may seal the perforation. Iliofemoral dissection is usually retrograde and does not limit flow, but severe dissections may be flow-limiting or even occlusive. Flow-limiting dissections should be treated with endovascular or surgical repair. Suture-mediated, severe stenosis of the common femoral artery at the access site often responds to gentle balloon dilation, which does not need to completely eliminate the narrowing to be successful: mild to moderate residual narrowing is rarely symptomatic.

Aortic annulus rupture, a rare occurrence, is associated with high mortality. Independent predictors of this complication include valve oversizing and the presence of moderate or severe calcification in the left ventricular outflow tract.⁵⁶ It may present subtly with thickening of the interatrial septum on echocardiography and subsequent development of pericardial effusion. Effusion may be treated with pericardiocentesis, and surgical repair may be considered. Immediate treatment with protamine and blood pressure control are recommended for conservative management.

In the meta-analysis by Genereux and colleagues, the overall incidence of bleeding was 41% (life-threatening, 16%).⁵⁷ Life-threatening bleeding is associated with a 6 to 9 times increase in 30-day mortality after TAVR and was an independent predictor of 1-year mortality. The TA route for TAVR has consistently been reported as an independent predictor of life-threatening bleeding.⁵⁸

Aortic Insufficiency

Acute, moderate, or severe prosthetic aortic regurgitation after TAVR will be paravalvular, transvalvular, or mixed. The 2- and 3-year follow-up of the PARTNER trial using the balloon-expandable valves resulted in significantly worse PVL than SAVR with more than 50% of TAVR patients experiencing at least mild PVL.^{16,19,59} There has been much focus on the effect of aortic regurgitation on survival following TAVR. A number of studies have identified aortic regurgitation higher than grade 2+ to be an independent predictor of short- and long-term mortality.⁶⁰ The direct causal relationship between PVL and mortality still needs to be determined, as does the significant heterogeneity in the assessment of PVL; thus far controversy regarding the use of echocardiography or magnetic resonance imaging continues.⁶¹ The use of cross-sectional CT has improved the accuracy of aortic annular sizing for TAVR and has led to the overall reduction of PVL, displacing two-dimensional TTE as the gold standard for TAVR valve selection.⁶²

Acute transvalvular regurgitation may occur as a result of incomplete valve closure when the valve is deployed in the setting of systemic arterial hypotension and this improves when the blood pressure is increased. The valve also may simply require a brief period of time (minutes) to “warm up” and achieve full leaflet mobility. A third scenario for transvalvular aortic regurgitation is that it may be caused by an overhanging native aortic leaflet, which can prevent closure of the TAVR valve leaflets. In this case, the operator can attempt to close the TAVR valve leaflets by placing an angled-pigtail catheter in each aortic cusp. If this is unsuccessful, another TAVR valve should be deployed just aortic to the initial TAVR valve to adequately displace the native aortic leaflets.

The more common scenario includes that of the paravalvular aortic leak. For patients with more than mild PVL noted during the procedure, the position of the transcatheter heart valve should be assessed. If the valve is malpositioned, a second valve may be implanted in the first valve. However, if the valve is well positioned, dilating the stent-valve with a balloon catheter may expand the valve and fill the annulus more completely. Chronic, moderate, or severe paravalvular aortic regurgitation after TAVR may be treated percutaneously by implantation of a second valve or by implantation of one or more vascular plugs.

Valve Embolization

Valve embolization is most commonly caused by loss of capture during rapid ventricular pacing (leading to ejection of the incompletely deployed valve from the annulus), but it also may be caused by malpositioning or, in rare cases, choosing a valve too small for the annulus. Embolization is best avoided by confirmation of stable pacing and by careful valve positioning prior to and during slow, controlled deployment. In the event of aortic movement during deployment, the valve may be immediately pushed back into the annulus if the deploying operator has maintained pressure on the inflation syringe (to hold the no-longer-crimped valve on the partially inflated balloon)

without further inflation or deflation. If the valve cannot be pushed back across the annulus, then it may be pulled into the arch (and ideally into the descending aorta) before being deployed. If the deployment balloon has been deflated, the valve will be loose on the wire and should be recaptured with the balloon and deployed in a safe location, either just distal to the left subclavian artery or immediately proximal to the common iliac bifurcation. Wire position across the valve must be maintained to prevent the valve from turning and obstructing the aorta. After the embolized valve is secured, a second valve may be implanted in the annulus to complete the TAVR. Valve embolization into the left ventricle is less common and almost always requires surgical intervention.

Coronary Occlusion

Myocardial infarction is a rare yet catastrophic complication during TAVR and occurs in less than 1% of patients.^{11,63} Acute, aorto-ostial coronary occlusion may be treated effectively with immediate percutaneous coronary intervention (PCI) or emergent peripheral cardiopulmonary bypass followed by PCI. Left main coronary artery occlusion is most likely, although right coronary artery obstruction has also been described. Most commonly, patients experience acute hemodynamic compromise with ST-segment elevation suggesting acute myocardial infarct. Percutaneous intervention can be facilitated in high-risk cases by placing a 0.014-inch coronary interventional wire and/or balloon into the coronary artery at risk prior to deployment of the new valve (Fig. 79-19). Prevention remains the mainstay of treatment for this dreadful complication. Coronary artery orifice less than 12 mm as determined by a high-definition CT scan should prompt concern. In such scenarios, performing a BAV with a concomitant root angiogram may discern the potential for main coronary artery occlusion.

FIGURE 79-19 ■ Left main coronary wire during valve-in-valve deployment.

Conduction Abnormalities

Transcatheter aortic valves intentionally oversize the aortic annulus and are partially placed in a subannular position, bringing them into proximity with the cardiac conduction system as it enters the ventricular septum. The need for a pacemaker post TAVR is infrequent with the Edwards-SAPIEN valve reported at 3.4% in the randomized PARTNER US trial.^{11,15} There remains an important difference in the need for permanent pacemakers after TAVR between the balloon-expandable (6.5%) and self-expanding valves (25.8%).^{64,65}

Complete heart block following TAVR is immediately treated by backup pacing from the temporary pacing wire. The bradyarrhythmia may be transient and the temporary wire may be left in place until the question of need for permanent pacing has been elucidated.

New left bundle branch block (LBBB) occurred in 121 of 1151 (10.5%) patients and persisted in more than half at 6 months to 1 year according to the PARTNER trial data.⁶⁶ New LBBB was not associated with significant differences in 1-year mortality, cardiovascular mortality, repeat hospitalization, stroke, or myocardial infarction. However, it was associated with increased permanent pacemaker implantation during hospitalization (8.3 vs. 2.8%, $P < 0.005$) and from discharge to 1 year (4.7 vs. 1.5%; $P < 0.01$). The ejection fraction failed to improve after TAVR in patients with new LBBB and remained lower at 6 months to 1 year (52.8 vs. 58.1%; $P < 0.001$).⁶⁶

Uncommon Complications

Other uncommon complications reported include tamponade and mitral valve injury. Tamponade can result from cardiac perforation in the right ventricle during placement of the pacemaker and the left ventricle by the stiff wire used for the BAV and TAVR. Large inspiratory drops in systemic arterial pressure (pulsus paradoxus) suggest a hemodynamically significant effusion, which can be confirmed with echocardiography. Treatment with pericardiocentesis is reasonable because the bleeding into the pericardium is often self-limited. If blood loss is substantial, blood may be autotransfused from the pericardium into a systemic vein while preparation is made for surgical exploration. The site of perforation may not be identifiable at surgery.

The mitral valve, including the chordae, may be damaged by guidewires in the left ventricle. Furthermore, the anterior leaflet of the mitral valve can be impinged on by a transcatheter heart valve placed too low in the ventricle. If severe mitral valve damage has occurred, operative interventions are the treatment of choice. Luckily, this is an extremely rare complication.

FUTURE DIRECTIONS

Catheter-based treatment options for patients with structural heart disease are rapidly improving with experience. Although the first randomized trials in North America have only recently been completed, the next generation of TAVR valves has grown immensely around the world.

Devices have been developed to decrease the known TAVR complications, including PVL and embolization. Technology now allows device repositionability and redeployment. The lower profile sheaths and valves will allow more transfemoral access and potentially reduce the need for alternative access devices. Lastly, the use of TAVR in intermediate-risk patients is forthcoming with the completion of the randomized PARTNER 2 intermediate trial with the SAPIEN XT valve and the ongoing SURTAVI trial with the CoreValve system.

ANATOMY

The mitral valve apparatus is composed of the mitral annulus, leaflets, chordae tendineae, papillary muscles, and the left ventricular lateral wall (Fig. 80-1). Chordae tendineae and papillary muscles comprise the subvalvular apparatus.

Annulus

The right fibrous trigone is a dense fibrous area of continuity between the annuli of the mitral, tricuspid, and noncoronary cusp of the aortic valve, as well as the membranous interventricular septum. The left fibrous trigone forms the leftmost border of fibrous continuity between the aortic and mitral valves. The mitral valve leaflets are attached to an ovoid ring, or annulus of fibrous tissue, that extends from the right and left fibrous trigones to form the junction between the left atrium and ventricle. In three-dimensional space, the annulus maintains a hyperbolic paraboloid shape (saddle shape).¹ The mid-anterior and mid-posterior annular segments are highest

(farthest away from the ventricular apex), whereas the anterolateral and posteromedial commissures are lowest. The mitral annulus is thinnest at the insertion site of the posterior leaflet. As this segment is not attached to any rigid cardiac structures, it is the most mobile throughout the cardiac cycle and is the most prone to annular dilation.

Leaflets

The mitral valve has two major leaflets: the larger anterior (aortic) leaflet and the smaller posterior (mural) leaflet. The anterior leaflet is semicircular and is attached to one third of the annular circumference. The leaflet free edge does not have indentations. The anterior leaflet defines the boundary between the inflow and outflow tracts of the left ventricle. The posterior leaflet is quadrangular and is attached to two thirds of the annular circumference. The leaflet typically contains three or more scallops separated by fetal clefts or subcommissures, which develop to variable degrees in each individual.²

The subcommissures of the posterior leaflet permit further division of the mitral valve into eight segments (Fig. 80-2). The three posterior leaflet scallops are anatomically termed *anterolateral* (P1), *middle* (P2), and *posteromedial* (P3) segments. The three corresponding segments of the anterior leaflet are the anterior segment (A1), middle segment (A2), and posterior segment (A3). The anterolateral and posteromedial commissures comprise the remaining two segments. The posteromedial and anterolateral commissures are identified by the axis of the corresponding papillary muscles and the commissural chordae. The distance between the free edge of the commissures and the annulus is approximately 8 mm. As such, during open commissurotomy it is important to maintain this distance to reduce the risk of leaflet tearing and subsequent mitral regurgitation.

The atrial surface of the leaflets is divided into two zones: a marginal rough zone and central smooth zone. The rough zone is the coaptation surface of the valve and is the insertion site of most of the chordae tendineae.

Chordae Tendineae

The chordae tendineae are collagenous leaflet extensions connecting the papillary muscles and the ventricular side of the leaflets (Fig. 80-3). Chordae are classified based on

FIGURE 80-1 ■ Surgical anatomy of the mitral valve and other important neighboring structures.

FIGURE 80-2 ■ Segmental anatomy of the mitral valve from the surgical view is demonstrated (A) grossly and (B) with three-dimensional transesophageal echocardiography. (Modified from Debonnaire P, Palmen M, Marsan NA, et al: Contemporary imaging of normal mitral valve anatomy and function. *Curr Opin Cardiol* 27:457, 2012.)

FIGURE 80-3 ■ Subvalvular apparatus. Primary chordae are attached to the free margin of the leaflet, secondary chordae are attached to the ventricular surface of the leaflet body, and tertiary chordae are attached to the ventricular surface of the leaflet base.

the site of insertion on the leaflet. Primary chordae insert on the leaflet free margin and act to prevent leaflet prolapse. Secondary chordae insert on the ventricular surface of the leaflets and reduce excess tension on the leaflet tissue. Tertiary chordae connect the leaflet base to the

mitral annulus and surrounding myocardium. Tertiary chordae are limited to the posterior leaflet of the mitral valve. Often, the diameter of the chordae increases from the leaflet edge to the annulus.

Papillary Muscles and Left Ventricular Wall

Two papillary muscles arise between the middle and apical thirds of the left ventricle. The anterolateral papillary muscle is typically composed of one muscle body while the posteromedial papillary muscle usually arises from two muscle bodies. Each papillary muscle supplies chordae to both leaflets. The anterolateral papillary muscle receives blood from both the left anterior descending artery as well as a diagonal or obtuse marginal branch of the circumflex artery. However, the posteromedial papillary muscle receives blood from only one source: either the circumflex or right coronary artery. Consequently, the posteromedial papillary muscle is more sensitive to myocardial ischemia than the anterolateral papillary muscle. As the lateral wall of the left ventricle supports the base of the papillary muscles, it may also be considered part of the mitral valve apparatus. In fact, the left ventricular lateral wall is integral in the pathogenesis of ischemic mitral regurgitation.

MITRAL STENOSIS

Pathophysiology

In non-diseased adult human hearts, the normal mitral valve area is 4 to 6 cm². Once the mitral valve orifice narrows to less than 2.5 cm², a pressure gradient is necessary to generate blood flow from the left atrium into the

TABLE 80-1 Classification of Mitral Stenosis Severity

Findings	Mild	Moderate	Severe
Specific			
Valve area (cm ²)	>1.5	1.0-1.5	<1.0
Supportive			
Mean gradient (mm Hg)*	<5	5-10	>10
Pulmonary artery pressure (mm Hg)	<30	30-50	>50

*At heart rates between 60 and 80 beats/min and in sinus rhythm.

From Baumgartner H, Hung J, Bermejo J, et al: Echocardiographic assessment of valve stenosis: EAE/ASE recommendations for clinical practice. *J Am Soc Echocardiogr* 22:17, 2009.

left ventricle. Based on a semi-quantitative grading system, mitral stenosis is typically classified as mild if the valve area is >1.5 cm², moderate when the valve area is between 1.0 and 1.5 cm², and severe when the valve area is <1.0 cm² or the mean transvalvular pressure gradient exceeds 10 mm Hg (Table 80-1). However, it should be noted that the definition of *severe mitral stenosis* used by the American College of Cardiology/American Heart Association (ACC/AHA) is based on the severity at which symptoms occur as well as the severity at which intervention will improve symptoms (in essence, “severe” in professional society guidelines should be read as “significant”).³ Thus, in the 2014 iteration of the ACC/AHA guidelines, a mitral valve area of 1.5 cm² or less and a mean transvalvular gradient between 5 and 10 mm Hg is considered severe.

The transvalvular gradient results in elevated left atrial and pulmonary venous pressures. Over time, pulmonary artery hypertension develops from a combination of compensatory arterial vasoconstriction, intimal hypertrophy of the pulmonary arterioles and obliterative change, and passive retrograde transmission of the elevated pulmonary venous pressure. Pulmonary edema results when pulmonary venous pressure exceeds plasma oncotic pressure. At rest, mitral stenosis is often asymptomatic; however, any increase in flow across the mitral valve or decrease in duration of diastole results in an increase in the transvalvular pressure gradient. Consequently, dyspnea is typically precipitated by exercise, stress, infection, pregnancy, or rapid atrial fibrillation.

As pulmonary artery pressures rise, both right ventricular end-diastolic pressure and volume increase, resulting in right ventricular dilation and tricuspid regurgitation. Because left ventricular inflow is restricted, left ventricular chamber size or end-diastolic volume is normal or less than normal, and end-diastolic pressure is generally low. Although most patients with mitral stenosis have normal left ventricular dimensions and systolic function, ejection fraction is significantly reduced in a small proportion of patients (generally older adults).⁴ These patients often have severe segmental wall contraction abnormalities of the posterobasal or anterolateral segments likely from papillary muscle fibrosis and immobilization.^{4,5} Diffuse hypokinesis has also been described and is likely due to a chronic low cardiac output state.

Etiology

Although the prevalence of rheumatic disease has markedly decreased in recent decades, particularly in developed nations, it remains the predominant cause of mitral stenosis in the United States and worldwide.⁶ However, only half to two thirds of patients report a definite history of rheumatic fever, with at least a 2:1 female-to-male predominance. Rheumatic valve disease is generally acquired before age 20, and becomes clinically evident one to three decades later.⁷ Nonrheumatic etiologies of mitral stenosis include severe mitral annular calcification (common in older people), congenital mitral valve deformities, carcinoid syndrome, systemic lupus, neoplasm, and prosthetic valve calcification.

Rheumatic heart disease is an insidious fibrotic process that affects all segments of the mitral apparatus, as well as other valves. Mimicry between group A streptococcal antigens and epitopes found on human tissue stimulate autoimmune mediated damage to cardiac tissue.⁶ The mitral valve is the most commonly affected (isolated mitral stenosis is found in 40% of patients), followed by concomitant aortic and mitral valve disease, and least frequently isolated aortic valve disease. Early valvular lesions include: (1) leaflet thickening; (2) chordal thickening, fusion, and shortening; and (3) commissural fusion (Fig. 80-4). Progressive valvulopathy produces a characteristic “fish mouth” single central opening, with restricted leaflet motion during systole and diastole. Chordal thickening and fusion can create a dense fibrotic subvalvular mass that can further obstruct forward flow. Calcification, particularly at the commissural edges and occasionally extending posteriorly into the annulus and subvalvular apparatus, is common late in the disease process and in older patients. These lesions, especially chordal fusion and shortening, often reduce leaflet coaptation by restricting leaflet mobility and thereby yield concomitant mitral regurgitation.

Clinical Characteristics and Diagnosis

The diagnosis of mitral stenosis can be based on medical history, physical examination, electrocardiography, chest radiography, echocardiography, and invasive hemodynamics. As explained previously, patients are most often women and are frequently asymptomatic, although symptoms can include fatigue, dyspnea, hemoptysis (from rupture of dilated bronchial veins), new onset atrial fibrillation, or systemic thromboembolism.

Patients with chronic severe mitral stenosis are often cachectic because of longstanding low cardiac output. In the absence of left ventricular dysfunction, peripheral pulses are normal and the apical impulse is in the standard position on chest palpation. A right ventricular parasternal heave is present in the setting of pulmonary hypertension. Auscultatory findings include a loud S₁, an opening snap, and a diastolic murmur. The diastolic murmur is a low-pitched rumble best heard at the apex. The early diastolic opening snap is generated by sudden tensing of the pliable leaflets during valve opening and is absent later in the disease when the leaflets are immobile. The electrocardiogram may be normal but often

FIGURE 80-4 ■ Pathologic changes of the mitral valve in mitral stenosis. Thickened, rigid, nodular appearance of the mitral valve leaflets as viewed from the atria (**A**) and ventricle (**B**). The commissures are calcified and fused, thereby creating the characteristic “fish mouth”-shaped valve. **B** and **C**, The subvalvular apparatus is thickened, fused, and shortened. **D**, Healthy mitral valve leaflets. (From Chandrashekar Y, Westaby S, Narula J: Mitral stenosis. *Lancet* 374:1273, 2009.)

demonstrates P-wave abnormalities indicative of left atrial enlargement (biphasic P-wave in lead V_1 ; or broad, notched P-wave in lead II), atrial fibrillation, or right ventricular hypertrophy (right-axis deviation, and a tall R-wave in lead V_1). The chest radiograph may be normal; however, a large left atrium is frequently seen. In patients with severe mitral stenosis and pulmonary hypertension, the right atrium and ventricle may also be enlarged.

Echocardiography has become the principle diagnostic method for assessing mitral valve disease. Echocardiography permits evaluation of the morphology, mobility, and extent of calcification of the mitral leaflets, commissures, and subvalvular apparatus. In addition, the severity of mitral stenosis can be assessed by measuring the mitral valve area, the transmitral gradient, left atrial size, and the pulmonary artery pressures (see [Table 80-1](#)). Transthoracic echocardiography also provides a noninvasive evaluation of other valves, as well as right and left ventricular function. Echocardiographic characteristics of the mitral valve apparatus are used to determine candidacy for percutaneous balloon valvuloplasty.

Left-sided heart catheterization is not usually necessary for diagnosis of mitral stenosis, but it can be useful when there is a discrepancy between data from noninvasive assessments. In patients that meet criteria for surgical intervention, cardiac catheterization should be performed to ascertain whether coronary artery disease is present. Right-sided heart catheterization is performed to measure the severity of pulmonary hypertension, and it can be used to determine reversibility after administration of pulmonary vasodilators.

Natural History

Although the average age of index cases of rheumatic fever is approximately 12 years, symptoms do not generally become apparent until 30 years of age.⁷ Once symptoms develop, progression to incapacitating disability occurs over approximately 10 years, and those with more severe symptoms have poorer prognoses ([Fig. 80-5](#)).⁸ As such, the development of symptoms is integral in the treatment decision-making process. In surgically

FIGURE 80-5 ■ Survival of patients with surgically untreated mitral stenosis stratified by symptom severity at initial evaluation. *Grade 1*, Asymptomatic; *Grade 2*, mild symptoms; *Grade 3*, moderate or moderately severe symptoms. (From Rowe JC, Bland EF, Sprague HB, et al: The course of mitral stenosis without surgery: ten- and twenty-year perspectives. *Ann Intern Med* 52:741–749, 1960.)

untreated patients with mitral stenosis, the average age of death is between 40 and 50 years.^{8,9}

Various sequelae often develop during the course of surgically untreated mitral stenosis that shorten the interval between symptom onset and death. Left atrial hypertension ultimately distorts atrial cardiomyocyte architecture and predisposes patients to atrial fibrillation. The onset of atrial fibrillation often initiates symptoms because patients with mitral stenosis rely heavily on atrial contraction for ventricular filling, and rapid heart rates reduce the duration of diastole. Consequently, cardiac output declines and left atrial pressure rises. In fact, atrial fibrillation incrementally increases the risk of death in patients with surgically untreated mitral stenosis; 20-year survival was 10% in patients with atrial fibrillation compared with 29% in those in sinus rhythm.¹⁰

Systemic thromboembolism also significantly alters the course of the disease, particularly when it results in stroke. Although most emboli originate in the left atrial appendage or left atrium, atrial fibrillation is not prerequisite for thrombus formation in surgically untreated mitral stenosis. Overall, arterial thromboembolization occurs in at least 10% of surgically untreated patients with mitral stenosis.¹¹

Pulmonary hemorrhage infrequently can develop in even mildly symptomatic patients, but the risk remits after surgical correction of the stenotic valve. Finally, infective endocarditis is uncommon in patients with mitral stenosis.

It is important to emphasize that these data and complicating events correspond to medically treated and surgically untreated patients with mitral stenosis. In fact, progression from initial symptoms to death was likely much shorter before medical therapies such as diuretics were developed. Similarly, surgical treatment has significantly altered the disease course. The increased life expectancy of such patients after surgical correction of mitral stenosis has resulted in the manifestation of late

significant rheumatic aortic valve disease and late secondary tricuspid regurgitation.

Indications for Surgery

Untreated mitral stenosis is associated with a poor prognosis once severe symptoms occur.¹² Percutaneous balloon mitral commissurotomy is the first-line therapy for mitral stenosis in patients with favorable anatomy. This procedure is indicated in symptomatic patients (stage D) with isolated severe mitral stenosis (mitral valve area ≤ 1.5 cm²; Fig. 80-6).³ Left atrial thrombus and greater than mild mitral regurgitation are contraindications to balloon commissurotomy. Percutaneous balloon commissurotomy may also be appropriate in asymptomatic patients with severe mitral stenosis (valve area < 1.0 cm²) and in those with severe mitral stenosis and new onset atrial fibrillation. Finally, balloon commissurotomy can be considered in symptomatic individuals with mitral valve area greater than 1.5 cm² if there is hemodynamic evidence of significant mitral stenosis with exercise (e.g., pulmonary capillary wedge pressure > 25 mm Hg). The Wilkins scoring system grades mitral valve morphology by use of echocardiography (Table 80-2). Four characteristics, graded on a scale from 0 to 4, are assessed: leaflet mobility, leaflet thickening, valve calcification, and extent of subvalvular disease. A total score greater than 8 is predictive of low success with percutaneous balloon mitral commissurotomy.^{13,14} Percutaneous balloon commissurotomy is associated with recurrent mitral stenosis, especially in patients undergoing repeat procedures for recurrence, as well as iatrogenic mitral regurgitation, particularly in patients with high Wilkins scores.¹⁴

Mitral valve surgery is an established therapy for mitral stenosis that predates balloon commissurotomy. Surgical options include commissurotomy (either closed or open, the latter permitting more extensive surgery under direct visualization) or mitral valve replacement. Because of the insidious nature of mitral stenosis and evidence that mitral stenosis does not have longstanding detrimental effects on the left ventricle, surgery should be delayed until the patient has severe, limiting symptoms (New York Heart Association [NYHA] class III or IV).³ Thus, mitral valve surgery is indicated in severely symptomatic patients (NYHA class III or IV) with severe mitral stenosis (mitral valve area ≤ 1.5 cm²) who are not high risk for surgery and who are not candidates for or who have failed previous percutaneous balloon mitral commissurotomy (see Fig. 80-6).³ Concomitant mitral valve surgery is also recommended in patients with severe mitral stenosis undergoing cardiac surgery for other primary indications.

MITRAL REGURGITATION

Pathophysiology

Mitral regurgitation, the retrograde ejection of blood from the left ventricle into the left atrium during systole, may be acute, chronic and compensated, or chronic and

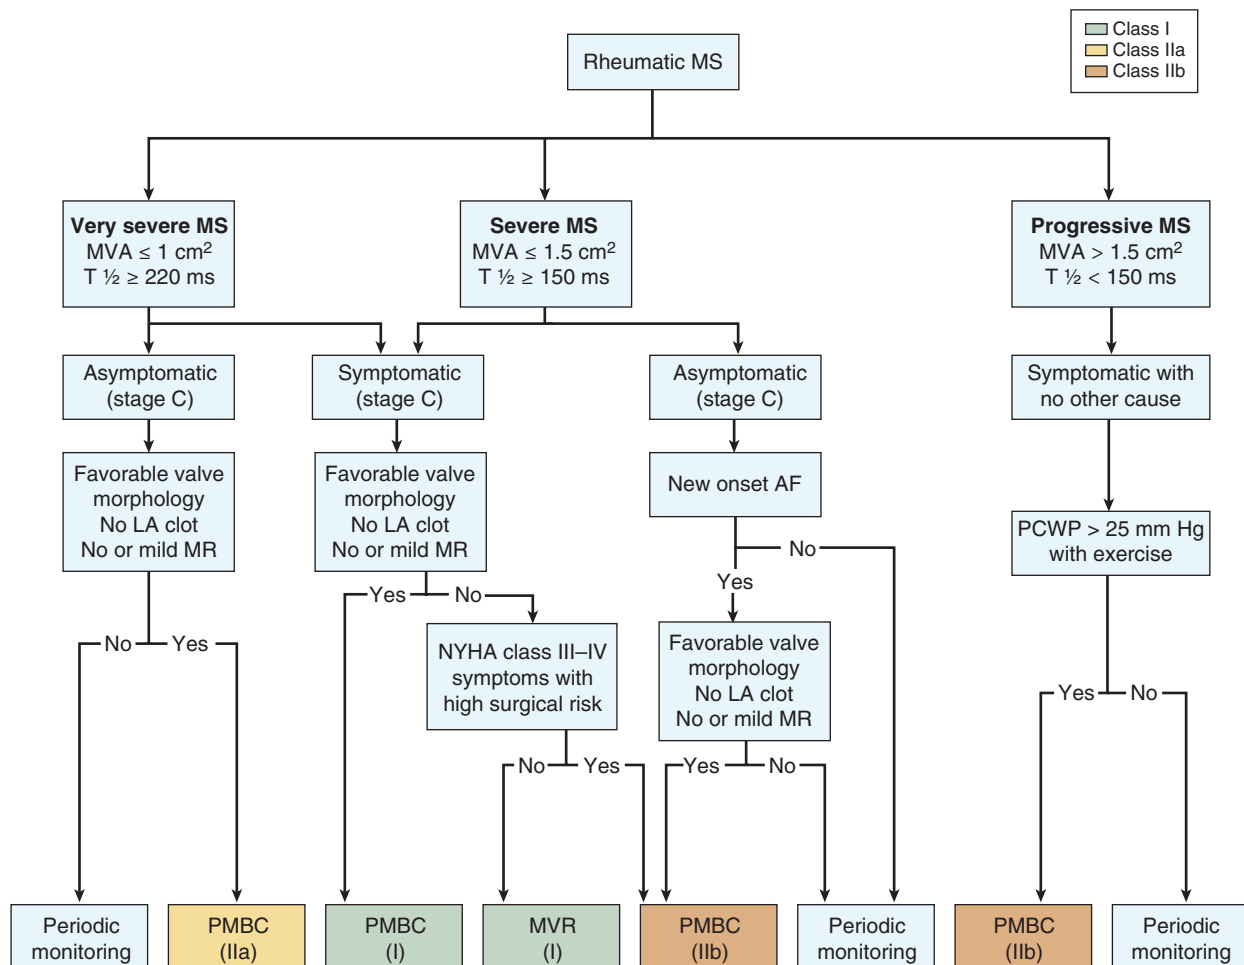

FIGURE 80-6 ■ Indications for intervention for mitral stenosis. AF, Atrial fibrillation; LA, left atrial; MR, mitral regurgitation; MS, mitral stenosis; MVA, mitral valve area; MVR, mitral valve surgery (repair or replacement); NYHA, New York Heart Association; PCWP, pulmonary capillary wedge pressure; PMBC, percutaneous mitral balloon commissurotomy; T ½, pressure half-time. (From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC Guideline for the Management of Patients with Valvular Heart Disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 129:e554, 2014.)

TABLE 80-2 Assessment of the Mitral Valve with the Wilkins Score

Grade	Mobility	Thickening	Calcification	Subvalvular Thickening
1	Highly mobile valve with only leaflet tips restricted	Minimal leaflet thickening (4-5 mm)	Single area of increased echo brightness	Minimal thickening just below the mitral leaflets
2	Leaflet mid and base portions have normal mobility	Midleaflets normal, considerable marginal thickening (5-8 mm)	Scattered areas of brightness confined to leaflet margins	Thickening of chordal structures extending to one-third the chordal length
3	Valve continues to move forward in diastole, mainly from the base	Entire leaflet thickened (5-8 mm)	Brightness extends into mid-portion of leaflets	Thickening extended to distal third of the chords
4	No or minimal forward movement of the leaflets in diastole	Considerable thickening of entire leaflet (>8-10 mm)	Extensive brightness throughout much of the leaflet tissue	Extensive thickening and shortening of all chordal structures that extends to the papillary muscles

Total score is the sum of the four items and ranges between 4 and 16.

Modified from Baumgartner H, Hung J, Bermejo J, et al: Echocardiographic assessment of valve stenosis: EAE/ASE recommendations for clinical practice. *J Am Soc Echocardiogr* 22:14, 2009.

decompensated. The new low resistance, regurgitant pathway results in volume overload of the left ventricle at end diastole (increased preload) as well as in a reduction of afterload.¹⁵ Subsequently, a larger volume of blood is ejected from the left ventricle with each contraction. However, the effective forward stroke volume and cardiac output actually decrease because a proportion of the blood volume is ejected retrograde into the left atrium. Volume overload in the left atrium increases left atrial pressure from a normal level of approximately 10 mm Hg to as high as 25 mm Hg. The increased preload ultimately induces ventricular remodeling through eccentric hypertrophy and dilation.¹⁵ A larger ventricular cavity allows for an increase in total stroke volume, thereby maintaining forward stroke volume at near normal levels. This is chronic compensated mitral regurgitation.

Because the annulus is continuous with the left ventricle, annular dilation results from ventricular enlargement. The normal ratio between the anteroposterior and transverse diameters of the mitral annulus is 3:4 in systole. In chronic mitral regurgitation, this ratio is inverted, impairing proper leaflet coaptation and generating regurgitant flow even in the absence of leaflet prolapse. Annular dilation affects the posterior annulus to a greater extent than the anterior annulus.

Similar to ventricular compensation via enlargement, the left atrium dilates to accommodate the volume overload at lower filling pressures.¹⁵ Atrial enlargement increases the risk of atrial arrhythmias, such as atrial fibrillation and consequent mural thrombi from stasis. When mitral regurgitation develops suddenly from chordal rupture, papillary muscle infarction, or leaflet perforation, there is inadequate time for left atrial and

ventricular compensation. Thus, patients with acute mitral regurgitation typically present in a state of acute pulmonary edema and cardiogenic shock.

Ultimately, volume overload and eccentric ventricular hypertrophy impair ventricular performance and prevent effective ventricular contraction; this is chronic decompensated mitral regurgitation. Stroke volume and cardiac output decline as blood preferentially flows retrograde into the lower resistance pathway. Consequently, the pressure in the left atrium and pulmonary vasculature increases. Untreated decompensated mitral regurgitation progresses to irreversible pulmonary hypertension, pulmonary edema, and congestive heart failure. The presence of left ventricular dysfunction portends a worse prognosis regardless of the treatment modality. Although ventricular reverse remodeling can follow surgical correction of mitral regurgitation, it remains evident that normalization of cardiac dimensions is less likely or impossible once the ventricle has enlarged to a certain extent.¹⁶

Functional Classification

A thorough description of valve disease should incorporate the pathophysiologic triad first proposed by Carpentier (Table 80-3).¹⁷ The triad includes etiology (cause of the disease), valve lesions (structural changes resulting from the disease process), and leaflet dysfunction (alterations in leaflet motion resulting from the structural lesion). This classification scheme is emphasized because prognosis is etiology dependent, treatment strategy is determined by the type of valve dysfunction, and different surgical techniques are selected for specific valve lesions.

TABLE 80-3 Pathophysiologic Triad of Mitral Regurgitation

Dysfunction	Lesions	Etiology
Type I		
Normal leaflet motion	Annular dilation	Ischemic cardiomyopathy Dilated cardiomyopathy Permanent atrial fibrillation Endocarditis
	Leaflet perforation	
Type II		
Increased leaflet motion above annular plane (leaflet prolapse)	Chordal elongation or rupture	Degenerative disease Fibroelastic deficiency Barlow's disease Marfan syndrome Endocarditis Rheumatic Trauma
	Papillary muscle elongation or rupture	Ischemic cardiomyopathy Barlow's disease (elongation)
Type IIIa		
Restricted leaflet motion (systole and diastole)	Leaflet thickening or retraction Chordal thickening, retraction, or fusion Commissural fusion	Rheumatic disease Carcinoid heart disease Mitral annular calcification
Type IIIb		
Restricted leaflet motion (systole only)	Papillary muscle displacement Leaflet tethering	Ischemic cardiomyopathy Dilated cardiomyopathy Submitral ventricular aneurysm

The mechanism of mitral regurgitation can be categorized using Carpentier's functional classification (Fig. 80-7).¹⁷ The classification system is compartmentalized according to variations in leaflet motion. In type I dysfunction, leaflet motion is normal and a central mitral regurgitation jet is generated by annular dilation or leaflet perforation. Type II dysfunction describes leaflet prolapse, where the free margin of one or both leaflets rises above the annular plane in systole. Such leaflet dysfunction is most commonly due to chordal elongation or rupture, followed by papillary muscle elongation and rupture. In type III dysfunction leaflet motion is restricted. Leaflet motion restricted during both diastole and systole is classified as type IIIa. Lesions commonly associated with rheumatic valvulitis are most often responsible for type IIIa dysfunction, including (1) leaflet thickening and retraction; (2) chordal thickening, shortening, or fusion; and (3) commissural fusion. As such, coexistent mitral stenosis is not uncommon in the setting of type IIIa mitral regurgitation. Type IIIb dysfunction describes leaflet motion restricted only during systole. Such dysfunction is the result of left ventricular dilation and subsequent leaflet tethering from papillary muscle displacement.

Etiology

Degenerative Disease

Systolic prolapse of a mitral valve leaflet is a relatively common and complex disease process. When severe, mitral prolapse begets significant mitral regurgitation, albeit infrequently (about 10% of patients).¹⁸ Nevertheless, degenerative mitral valve disease is the most common cause of isolated mitral regurgitation in the United States.^{19,20} Pathologic examination of degenerative mitral valves reveals mitral leaflet redundancy and myxomatous leaflet thickening that typically result from collagen replacement by acid mucopolysaccharides.²¹ Mutual support is lost as redundant and elongated leaflets improperly coapt during systole. Consequently, the leaflets extend into the left atrium and the valve is rendered regurgitant. Simultaneously, chordae are placed under abnormal strain. The chordae elongate and may ultimately rupture, generating more regurgitation. Annular dilation and calcification can also arise to varying extents and further contribute to the complexity of the mitral valve dysfunction.

FIGURE 80-7 ■ Carpentier's functional classification of mitral regurgitation: *Type I*, normal leaflet motion; *Type II*, increased leaflet motion resulting in prolapse; *Type III*, restricted leaflet motion; *IIIa*, during diastole and systole; *IIIb*, during systole only. The arrow demonstrates the direction of regurgitant flow in types I, II, and IIIb. In type IIIa, the arrow demonstrates the frequent association with coexistent mitral stenosis. (From Carpentier A, Adams DH, Filsoufi F: *Carpentier's reconstructive valve surgery*, St. Louis, 2010, Elsevier.)

FIGURE 80-8 ■ Surgical lesions in fibroelastic deficiency. **A**, Prolapse of P2 owing to multiple ruptured chordae; the leaflet tissue is thickened compared with other segments. Note the translucency of the anterior leaflet, and normal height and thickness of P1 and P3, in contrast to findings in Barlow's disease (see Fig. 80-9). **B**, Prolapse of P3 with ruptured chord. Note that P3 is thickened, but P2 and P1 are thin and of normal height. (From Anyanwu AC, Adams DH: Etiologic classification of degenerative mitral valve disease: Barlow's disease and fibroelastic deficiency. *Semin Thorac Cardiovasc Surg* 19:94, 2007.)

The spectrum of degenerative mitral valve disease is often subclassified into fibroelastic deficiency and Barlow's disease.²² In fibroelastic deficiency, or idiopathic chordal rupture, a considerable portion of leaflet tissue is unaffected by the myxomatous transformation (Fig. 80-8).²³ Typically, regurgitation is caused by rupture of a single chord that supports the posteromedial portion of the posterior leaflet (P2). Following rupture, the less supported leaflet segment becomes redundant and flail. More extensive posterior chordal rupture may sometimes occur. Patients with fibroelastic deficiency are characteristically older with a short history of mitral regurgitation.

On the opposite end of the degenerative mitral valve disease spectrum, Barlow's disease presents early in life, and most patients have a long history of a systolic murmur. Barlow's disease is characterized by extensive excess leaflet tissue in a dilated annulus (Fig. 80-9).^{21,22} Leaflet tissue is thickened, and there is marked redundancy in multiple segments. In addition, chordae and occasionally papillary muscles are thickened and elongated. Regurgitation is complex and secondary to multi-segment leaflet prolapse. *Forme fruste* valves share morphologic features of Barlow's disease and fibroelastic deficiency: multisegment thickening and prolapse within a smaller valve.

Rheumatic Disease

Progressive leaflet thickening and retraction, as well as chordal shortening and fusion from chronic valvulitis restrict leaflet motion during both diastole and systole, thereby rendering the valve regurgitant (see Fig. 80-4). The anterior leaflet is typically less thickened, and particularly in younger patients, elongated major chordae may allow regurgitation from anterior leaflet prolapse.²⁴ Annular dilation from extensive myocarditis may cause transient mitral regurgitation in the acute rheumatic

process. This mitral regurgitation can spontaneously regress after remission of the pancarditic acute rheumatic process.

Mitral Annular Calcification

Annular calcification is most often seen in older people.²⁵ Although it can occur without apparent disease of the leaflets or chordae, it may be more common in patients with myxomatous degeneration of the mitral leaflets. Calcifying disease of the annulus is a degenerative process that usually involves the posterior circumference of the annulus more than other portions.^{25,26} Annular calcification can extend into the adjacent myocardium of the left ventricle, and it yields mitral regurgitation through restricted motion of the posterior leaflet. Such calcification can substantially complicate mitral repair or replacement.^{25,27}

Infective Endocarditis

Endocarditis is a relatively uncommon cause of isolated mitral regurgitation compared with the frequency in which it is accountable for aortic regurgitation. Mitral valve endocarditis typically occurs in patients with an already structurally abnormal valve because of underlying degenerative or rheumatic valve disease. However, several virulent organisms, such as *Staphylococcus aureus*, may infect nondiseased valves.²⁸ *Staphylococci* and *Streptococci* now account for 80% of cases of endocarditis.^{28,29} Upon infection of a normal or abnormal mitral valve, mitral regurgitation can result from destruction of leaflet cusps, chordae, or both. Because of their spatial interrelatedness, aortic valve endocarditis may directly extend to the mitral valve as vegetations may drop down onto and infect the central portion of the anterior leaflet of the mitral valve (Fig. 80-10).³⁰

FIGURE 80-9 ■ Surgical lesions in Barlow's disease. **A**, Large valve with redundant, thick, bulky leaflets. **B**, Tall, posterior leaflet with tip rising to anterior annulus. **C**, Calcified anterior papillary muscle with fused, matted chords restricting the P1/P2 junction. **D**, Atrialization of the base of the posterior leaflet. Note the blurring of the atrial-leaflet junction with fissures and microthrombi (arrows). (From Anyanwu AC, Adams DH: Etiologic classification of degenerative mitral valve disease: Barlow's disease and fibroelastic deficiency. *Semin Thorac Cardiovasc Surg* 19:93, 2007.)

FIGURE 80-10 ■ Surgical lesions in ischemic cardiomyopathy and infective endocarditis. **A**, A dilated annulus with severe posterior leaflet tethering is characteristic of ischemic mitral regurgitation. **B**, Perforation (arrow) of the anterior leaflet of the mitral valve secondary to infective endocarditis.

Ischemic Cardiomyopathy

Left ventricular remodeling after myocardial infarction results in a conversion of the ventricular shape from ellipsoidal to spherical. Consequently, the papillary muscles are displaced, leading to restriction or tethering of posterior leaflet motion during systole (see Fig. 80-10).^{31,32} Leaflet coaptation surface area is compromised, resulting in mitral regurgitation. Furthermore, because of structural continuity between the ventricle and annulus, ventricular dilation leads to annular dilation that may exacerbate mitral regurgitation. Acute mitral regurgitation can result from ischemic papillary muscle dysfunction or rupture.³³ Occasionally, the papillary muscle will not rupture, but will become fibrotic and subsequently elongate, leading to leaflet prolapse.

Dilated Cardiomyopathy and Submitral Left Ventricular Aneurysms

The etiology of this disease is frequently idiopathic; however, known causes include chronic atrial fibrillation, myocarditis, excessive alcohol consumption, and immunologic abnormalities. Similar to ischemic cardiomyopathy, the natural history of the disease is often complicated by functional mitral regurgitation secondary to ventricular remodeling.

Submitral ventricular aneurysms can also result in mitral regurgitation. Such an aneurysm is not due to myocardial ischemia, and it occurs almost exclusively in Africa.³⁴ The aneurysm is generally situated directly beneath the posterior mitral leaflet; therefore, mitral regurgitation develops from aneurysmal distortion of the posterior leaflet.^{34,35}

Clinical Characteristics and Diagnosis

Chronic

Patients with chronic mitral regurgitation are often asymptomatic for years. During this time, left ventricular size can gradually increase and myocardial contractility declines. Ultimately, patients develop exercise intolerance and symptoms consistent with pulmonary venous hypertension. Fluid retention, chronic cardiac failure, and occasionally cardiac cachexia are representative of longstanding untreated disease. Coexistent secondary tricuspid regurgitation is frequently apparent at such late stages of the disease.³⁶

Similar to mitral stenosis, significant mitral regurgitation can generally be diagnosed on the basis of history, physical examination, electrocardiogram, and chest radiograph. On auscultation, a classic pansystolic murmur is appreciable, loudest at the apex, and radiates to the left axilla. However, murmurs may be heard in the parasternal aortic area or infrascapular–posterior cervical area in the setting of eccentric jets from posterior leaflet or anterior leaflet prolapse, respectively. An S₃ may be present because of augmented transmitral flow from volume overload and left ventricular dilation. In addition, lateral displacement of the left ventricular apical impulse from ventricular dilation and parasternal lift from

elevated pulmonary arterial pressures indicate more severe disease.

The electrocardiogram may remain unremarkable despite severe mitral regurgitation; however, evidence of ventricular hypertrophy or left atrial enlargement may also be present. Chest radiography in severe chronic mitral regurgitation may demonstrate left atrial and ventricular dilation (typically greater than in patients with mitral stenosis), and prominent pulmonary vasculature suggests the presence of pulmonary hypertension.

Two-dimensional echocardiography via transthoracic and transesophageal approaches delineate the mechanism and severity of mitral regurgitation (Table 80-4; Fig. 80-11). Echocardiography can also be used to assess left ventricular dimensions and global and regional contractility. Three-dimensional echocardiographic imaging techniques clearly identify leaflet pathology and specific areas of regurgitation within the mitral valve.³⁷ Novel magnetic resonance imaging techniques also accurately characterize anatomic and functional details of mitral valve dysfunction.

Mitral regurgitation can be characterized by left ventriculography. Leaflet prolapse can be visualized, and the degree of regurgitation can be estimated. Quantitative ventriculography permits calculation of regurgitant flow and left ventricular stroke volume, and forward flow can be assessed through measurement of cardiac output.³⁸ Furthermore, left heart catheterization is particularly useful to discern the extent of coronary artery disease, if present.

Acute

Mitral regurgitation can develop acutely because of chordal rupture or infective endocarditis or early in the evolution of acute myocardial infarction. Symptoms and signs are consistent with acute elevation of pulmonary venous pressures and low cardiac output. On auscultation, the murmur of mitral regurgitation is often midsystolic and higher pitched compared with the classic pansystolic murmur of chronic mitral regurgitation. The left atrium and left ventricle are normal in size because of inadequate time for compensation through dilation. Because of acute elevation of pulmonary venous pressure, significant pulmonary edema is often noted on chest radiography.

Natural History

Defining the natural history of mitral regurgitation is problematic because the disease etiology varies, age at onset varies, mitral regurgitation may not worsen for many years, and left ventricular function declines at different rates. It is important to note that left ventricular contractility is not truly assessed by ejection fraction. In fact, in the setting of mitral regurgitation, ventricular contractility often declines despite normal systolic function (ejection fraction) because part of the stroke volume is ejected retrograde into the low pressure left atrium. Ejection fraction does not actually decrease until later in the disease process. Patients with mitral regurgitation can

TABLE 80-4 Specific and Supportive Signs and Quantitative Parameters in Grading Mitral Regurgitation Severity

	Mild	Moderate	Severe
Specific Signs of Severity	Small central jet <4 cm ² or <20% of LA area* Vena contracta width <0.3 cm No or minimal flow convergence†	Signs of MR > mild present, but no criteria for severe MR	Vena contracta width ≥0.7 cm with large central MR jet (area >40% of LA) or with a wall-impinging jet of any size, swirling in LA* Large flow convergence† Systolic reversal in pulmonary veins Prominent flail MV leaflet or ruptured papillary muscle
Supportive Signs of Severity	Systolic dominant flow in pulmonary veins A-wave dominant mitral inflow‡ Soft density, parabolic CW Doppler MR signal Normal LV size§	Intermediate signs and findings	Dense, triangular CW Doppler MR jet E-wave dominant mitral inflow (E>1.2 m/sec)‡ Enlarged LV and LA size¶ (particularly when LV function is normal)
Quantitative Parameters†			
R Vol (mL/beat)	<30	30-44	45-59
RF (%)	<30	30-39	40-49
EROA (cm ²)	<0.20	0.20-0.29	0.30-0.39
			≥60 ≥50 ≥0.40

*At a Nyquist limit of 50-60 cm/sec.

†Minimal and large flow convergence radius <0.4 cm and ≤0.9 cm for central jets, respectively, with a baseline shift at a Nyquist of 40 cm/sec. Cutoffs for eccentric jets are higher and should be angle corrected.

‡Usually above 50 years of age or in conditions of impaired relaxation, in the absence of mitral stenosis or other causes of elevated LA pressure.

§LV size applied only to chronic lesions.

¶In the absence of other etiologies of LV and LA dilation and acute MR.

†Quantitative parameters can help to subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe as shown.

CW, Continuous wave; EROA, effective regurgitant orifice area; LA, left atrium; LV, left ventricle; MR, mitral regurgitation; MV, mitral valve; R Vol, regurgitant volume; RF, regurgitant fraction.

From Zoghbi WA, Enriquez-Sarano M, Foster E, et al: Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. *J Am Soc Echocardiogr* 16:777-802, 2003.

FIGURE 80-11 ■ Examples of color flow recordings of different mitral regurgitation (MR) lesions from the apical window. The case of mild regurgitation has no flow convergence and a small regurgitant jet area, in contrast to that of severe central MR, which shows a prominent flow convergence and large regurgitant jet area. The example with severe eccentric MR has a small jet area impinging on the wall of the left atrium but a large flow convergence and a wide vena contracta. (From Zoghbi WA, Enriquez-Sarano M, Foster E, et al: Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. *J Am Soc Echocardiogr* 16:784, 2003.)

also develop secondary tricuspid regurgitation, which also affects natural history.³⁶

Degenerative Disease

Degenerative disease, the most common organic mitral valve disease in the United States, occurs in approximately 2% to 3% of adults.^{19,20} However, many patients do not progress to developing significant regurgitation

requiring intervention. In fact, severe mitral regurgitation requiring valve repair or replacement is uncommon before the age of 50. Although the prevalence increases steeply thereafter, persons with mitral valve prolapse who reach age 70 still only have about a 5% chance of requiring mitral valve surgery.³⁹ Nevertheless, once significant mitral regurgitation develops, the disease progresses similarly to those with ruptured chordae and flail leaflets.

Once a diagnosis of flail leaflet is made, medical management typically is inadequate in improving patient symptoms and survival. Patients with surgically untreated mitral regurgitation because of flail leaflet have mortality rates significantly higher than expected (6.3% yearly).⁴⁰ Severe symptoms portend a worse prognosis as patients even transiently in NYHA class III or IV have much higher mortality rates (34% yearly), although the rate is notable even among those in NYHA class I or II (4% yearly).^{40,41} Essentially, surgery is almost unavoidable within 10 years after the diagnosis and is associated with an improved prognosis in patients with degenerative disease.

Ischemic Cardiomyopathy

The natural history of ischemic mitral regurgitation is covered in [Chapter 92](#). Because ischemic mitral regurgitation is a manifestation of a ventricular disease, it is not surprising that these patients typically have a significantly worse survival than those with degenerative disease.

Rheumatic Disease

Patients with surgically untreated but significant rheumatic mitral regurgitation demonstrate survival similar to those with rheumatic mitral stenosis.^{9,42} Likewise, the survival curves are considerably shorter in particular geographic areas and in certain races: 5-year survival after initial evaluation for rheumatic mitral regurgitation in the United States was 80% compared with 46% in Venezuela.⁴²

Infective Endocarditis

Infection of a previously mildly abnormal mitral valve can generate acute mitral regurgitation. The natural history of such a condition is similar to that of mitral regurgitation caused by chordal rupture. However, the early mortality is significantly higher as death can occur from overwhelming infection and sepsis.

Indications for Surgery

Intervention for patients with primary mitral regurgitation consists of either surgical mitral valve repair or replacement. Mitral valve repair is preferred over replacement if a successful and durable repair can be achieved. Reparability is dependent on valve morphology and surgeon expertise.³

Acute severe mitral regurgitation is an indication for urgent surgery. The indications for surgery in chronic severe mitral regurgitation have evolved during the last decade to reflect incremental improvements in the safety and efficacy of mitral valve repair as well as a better understanding of long-term outcomes in surgically untreated patients. Recommendations by the ACC/AHA for surgical intervention are predicated on symptoms, left ventricular dysfunction, atrial fibrillation, pulmonary hypertension, and valve reparability ([Fig. 80-12](#)).³

Symptoms

The onset of symptoms that results from severe mitral regurgitation worsens prognosis even when left ventricular function appears to be normal. This negative prognostic effect extends even to mild symptoms.⁴³ Thus, an increasing number of clinicians advocate operating earlier in less-symptomatic patients because NYHA functional class has been shown to be an independent predictor of postoperative mortality and left ventricular dysfunction.⁴⁴ Postoperative long-term survival is higher in patients in NYHA class I or II before surgery compared with those in class III or IV, (at 10 years, 76% vs. 48%), and operative mortality is lower (0.5% vs. 5.4%; [Fig. 80-13](#)).⁴³

Left Ventricular Dysfunction and Enlargement

Preoperative left ventricular dysfunction, as assessed by ejection fraction and end-systolic dimension, is one of the strongest predictors of survival, postoperative ventricular function, and functional status after surgery for chronic primary mitral regurgitation.^{43,45-48} Specifically, it has been reported that when the ejection fraction falls below 60%, mortality increases precipitously and prompt surgical referral is critical to outcome ([Fig. 80-14](#)).⁴⁵ Thus, the goal of therapy in mitral regurgitation is to correct it before the onset of left ventricular systolic dysfunction and the subsequent adverse effect on patient outcomes. Ideally, mitral valve surgery should be performed when the patient's left ventricle approaches but has not yet reached the parameters that indicate systolic dysfunction (left ventricular ejection fraction [LVEF] $\leq 60\%$ or left ventricular end-systolic dimension [LVESD] ≥ 40 mm), even if the patient is asymptomatic.³ Because symptoms do not always coincide with left ventricular dysfunction, imaging surveillance is used to plan surgery before ventricular function has severely deteriorated. Further delay, even though symptoms are absent, will lead to greater left ventricular dysfunction and an even worse prognosis. Although it is inadvisable to allow patients' left ventricular function to deteriorate beyond the benchmarks of an LVEF $\leq 60\%$ and/or LVESD ≥ 40 mm, some recovery of left ventricular function can still occur even if these thresholds have been crossed.

Atrial Fibrillation and Pulmonary Hypertension

In nonrheumatic mitral regurgitation, the onset of atrial fibrillation is in part due to enlarging left atrial size, and its presence worsens surgical outcome.^{40,49-51} Furthermore, the longer atrial fibrillation is present, the more likely it is to persist despite intervention. Therefore, it may be reasonable to restore mitral competence by low-risk repair with the hope that the ensuing reduction in left atrial size will help restore and maintain sinus rhythm. The ACC/AHA guidelines advocate surgery in asymptomatic patients with severe mitral regurgitation and new onset atrial fibrillation.³ However, restoration of sinus rhythm following valve surgery is uncertain, and concomitant surgical ablation of atrial fibrillation should be

FIGURE 80-12 ■ Indications for surgery for mitral regurgitation. AF, Atrial fibrillation; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; ERO, effective regurgitant orifice; HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; MR, mitral regurgitation; MV, mitral valve; MVR, mitral valve replacement; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume; Rx, therapy. *Mitral valve repair is preferred over MVR when possible. (From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC Guideline for the Management of Patients with Valvular Heart Disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 129:e569, 2014.)

a standard adjunct to patients with a history atrial arrhythmia. This strategy does not apply to rheumatic mitral regurgitation, in which active atrial inflammation can make restoration of sinus rhythm less likely and valve scarring reduces the likelihood of a successful repair. The presence of resting pulmonary arterial hypertension caused by mitral regurgitation is associated with poorer operative and long-term survival after valve surgery.^{46,52,53} Thus, it is reasonable to consider surgery in these asymptomatic patients if resting pulmonary artery systolic pressure exceeds 50 mm Hg and if there is a high likelihood of a successful and durable repair.³

Reparability

Mitral valve repair is preferred over replacement if a successful and durable repair can be achieved. Mitral valve repair is performed at a lower operative mortality rate

than replacement. Although no randomized trials exist for degenerative mitral valve disease, nearly every clinical report has demonstrated that operative risk for repair is approximately half that of replacement. Valve repair not only avoids the risks inherent to prosthetic heart valves, but it better preserves left ventricular function by preserving the subvalvular apparatus. In the case of posterior leaflet prolapse, repair has become sufficiently standardized so that repair is the standard of care. The ACC/AHA guidelines recommend that a successful repair rate of 90% or greater be the expectation of every cardiac surgeon who performs mitral valve procedures.³ Because the probability of successful mitral valve repair is strongly influenced by surgeon-specific mitral procedure volume,⁵⁴ it is recommended that more complex valves be referred to heart teams with particular expertise in this area.³

SURGERY

Anesthesia and Monitoring

Standard monitoring lines are used if the procedure is performed through a median sternotomy. A pulmonary artery catheter should be placed in cases of complex mitral valve surgery and multivalve surgery, as well as in high-risk operative candidates. Carbon dioxide insufflation is routinely used to facilitate deairing and reduce the risk of air embolism following aortic cross-clamp removal. A thorough transesophageal echocardiography study should routinely be performed before the initiation of cardiopulmonary bypass to characterize the mechanism and severity of mitral regurgitation, as well as other valve lesions. Transesophageal echocardiography also permits assessment of left ventricular function, quality of the repair, and extent of deairing. External defibrillator and cardioversion pads are placed in patients undergoing reoperative surgery.

If a right minithoracotomy is planned, the anesthesiologist should place a double-lumen endotracheal tube to permit left lung ventilation and right lung deflation.

Numbers at bottom indicate patients at risk. (From Tribouilloy CM, Enriquez-Sarano M, Schaff HV, et al: Impact of preoperative symptoms on survival after surgical correction of organic mitral regurgitation: rationale for optimizing surgical indications. *Circulation* 99:402, 1999.)

FIGURE 80-14 ■ Impact of preoperative left ventricular dysfunction on survival under conservative management for mitral regurgitation. **A**, All-cause mortality stratified by ejection fraction (EF). **B**, Association between EF and the risk of all-cause death under conservative management. Hazard ratio (solid line) and 95% confidence intervals (dashed lines) were estimated in a Cox multivariable model with ejection fraction represented as a spline function and adjusted for sex, comorbidity index, symptoms, and coronary artery disease. (Modified from Tribouilloy C, Rusinaru D, Grigioni F, et al: Long-term mortality associated with left ventricular dysfunction in mitral regurgitation due to flail leaflets: a multicenter analysis. *Circ Cardiovasc Imaging* 7:366, 2014.)

External defibrillator pads are placed under the right scapula and over the left anterolateral chest. If an endo-aortic balloon occlusion catheter will be used, bilateral radial arterial lines can be placed to facilitate rapid detection of balloon distal migration and innominate artery obstruction. Inadvertent balloon migration is not uncommon, and vascular injuries including aortic dissection have contributed to decreased utilization of this approach. Our institution prefers a transthoracic Chitwood aortic cross clamp and standard antegrade cardioplegia, retrograde cardioplegia, and right superior pulmonary vein venting cannulae placed across the chest wall or directly through the working incision. Thoracic epidural placement is not commonly used, because pain is reportedly mild after minithoracotomy incisions, particularly if rib spreading is avoided.

Surgical Approaches

Median Sternotomy

Median sternotomy is the most common surgical approach in mitral valve surgery.⁵⁵ Because it provides excellent access to all cardiac structures, it remains the surgical approach of choice in patients undergoing multivalve (other than concomitant mitral and tricuspid valve surgery) or combined mitral and coronary bypass grafting surgery. If a median sternotomy is the planned approach for mediastinal entry, then a Sarns 6-mm cannula is placed in the ascending aorta for arterial cannulation. 24 Fr superior vena cava and 28 Fr inferior vena cava metal tip cannulae are preferentially used for bicaval cannulation to maximize exposure and access to the mitral valve via Sondergaard's groove.

Minimally Invasive Approaches

Over the past 20 years, the increasing popularity of less invasive procedures has affected nearly every surgical specialty, including cardiac surgery. Advancements in imaging, surgical instrumentation, and robotic technology have enabled surgeons to perform complex cardiac surgical procedures through small incisions, often eliminating the need for sternotomy or cardiopulmonary bypass.⁵⁶⁻⁵⁹ In addition to benefits of improved cosmesis, minimally invasive mitral valve surgery was pioneered with the intent of reducing morbidity, postoperative pain, blood loss, hospital length of stay, and time to return to normal activity.⁶⁰⁻⁶³

Although initial reports of less invasive mitral valve surgery used parasternal^{61,64} or lower hemisternotomy⁶⁵ approaches for mediastinal access, the right anterolateral minithoracotomy has become the minimally invasive approach of choice for correcting mitral valve disease (Fig. 80-15).^{63,66,67} Compared with lower partial sternotomy, this approach provides a more en face view of the mitral valve and avoids surgery in the xiphisternal region, the area most prone to wound breakdown and infection following sternotomy. The right thoracotomy approach is considerably more resistant to infection because of overlying pectoralis muscle and soft tissue to seal the surgical site.⁶⁸ Robotic and port access mitral valve

FIGURE 80-15 ■ Surgical incisions. **A**, Conventional median sternotomy. **B**, Upper hemisternotomy. **C**, Lower hemisternotomy. **D**, Right minithoracotomy and groin incision for peripheral cannulation. Solid line represents skin incision and dotted line represents sternotomy.

surgery are thus performed through a 3- to 4-cm incision in the inframammary crease in female patients and just above the nipple in male patients, and the thoracic cavity is entered through the third or fourth interspace. Additional sub-centimeter ports facilitate introduction of a camera, left atrial retractor, suction, and in the case of robotic surgery, working arms (Fig. 80-16). Peripheral cannulation for cardiopulmonary bypass via the femoral arterial and venous vessels as well as the internal jugular vein facilitates smaller working incisions and less clutter of the surgical field. However, the ascending aorta and right atrium can be cannulated directly with the Seldinger technique if a contraindication precludes direct femoral cannulation. Aortic cross-clamping is achieved with a transthoracic Chitwood clamp or endovascularly with an endoaortic balloon occlusion device. Although beating- or fibrillating-heart strategies are used in some centers, concerns for higher stroke rates have led many surgeons to advocate using these techniques with caution.^{55,69} However, this risk is confounded by the nature of the patient for which these strategies must be used, such as patients with prior cardiac surgery, aortic pathology contraindicating cross-clamp application, or severe ventricular dysfunction. As robotic and thoracoscopic port access approaches facilitate all standard resectional and nonresectional valve repair techniques, the procedure of mitral valve repair is akin to the operation performed through conventional sternotomy.^{58,70-72}

Myocardial Management

Cardioplegic arrest is the most commonly used myocardial protection strategy during mitral valve surgery. Alternative techniques, such as beating heart and ventricular fibrillatory arrest, are occasionally used in select patients. Cardioplegic arrest uses cold blood high-potassium cardioplegia solution delivered via intermittent antegrade or combined antegrade and retrograde infusion. Further myocardial protection can be achieved with moderate systemic hypothermia and local hypothermia with topical ice.

Alternative protection strategies should be considered in certain clinical scenarios, such as in patients with severely depressed left ventricular function (beating heart) and severe atherosclerotic disease of the ascending aorta (beating heart or ventricular fibrillatory arrest). These alternative protection strategies are also useful in reoperative mitral valve surgery, when it may be difficult to cross-clamp the ascending aorta and when patent bypass grafts dissuade reoperative median sternotomy.

Operative Sequence in Context of Concomitant Procedures

When performing concomitant procedures, mitral valve surgery is typically performed at a specific juncture in the operation to accommodate anatomic constraints, facilitate operative flow, and avoid potential injury. Examples best illustrate these principles. When performing concomitant coronary bypass, the distal anastomoses are completed before mitral valve intervention. This avoids manipulation and anterior displacement of the heart after placement of a mitral prosthesis, which may beget posterior ventricular wall injury. When performing concomitant aortic valve replacement, the aortic valve leaflets are first resected and the annulus is débrided to avoid potential cutting of mitral annular sutures. The mitral procedure is performed before the aortic valve replacement

FIGURE 80-17 ■ Interatrial exposure of the mitral valve. **A**, Interatrial groove is dissected to fossa ovalis to expose roof of left atrium. **B**, Left atrium is incised and extended toward the superior and inferior vena cavae. **C**, Anterior retraction of the left atrium to expose the mitral valve.

because the aortic valve prosthesis distorts and obscures the anterior mitral annulus, particularly at the anterolateral commissure. When performing concomitant tricuspid valve surgery, a trans-septal approach is most efficient, and the mitral valve operation is conducted first. The interatrial septum is closed and the tricuspid annuloplasty can then be performed with the cross-clamp removed.

Exposure of the Mitral Valve

Excellent exposure of the mitral valve is essential before any mitral valve intervention. Various techniques have been described, including the interatrial approach through Sondergaard's (or Waterston's) groove, the right atrial trans-septal approach, and the left atrial dome approach.

Interatrial Approach through Sondergaard's Groove

The interatrial approach through Sondergaard's groove is the most commonly employed approach for mitral valve exposure (Fig. 80-17). First, the fatty tissue just anterior to the right superior and right inferior pulmonary veins is dissected, essentially separating the right atrium from the anterior surface of the left atrium. It is important to start this incision on the actual body of the left atrium to avoid any potential involvement of the pulmonary venous ostia. If this incision is extended too medially, the right atrium can be entered accidentally. This issue can be addressed easily with caval tapes or vacuum assisted venous return. Generally, it is not necessary to add additional time to close the inadvertent right atriotomy separately because it can be incorporated in the

left atriotomy closure at completion of the mitral operation. If extensive exposure is necessary, the posterior aspect of the superior vena cava can be dissected from the left atrium to free additional portions of the roof of the left atrium for atriotomy.

Right Atrial Trans-septal Approach

In this approach, bicaval cannulation and caval snaring with tapes are generally helpful. The right atriotomy is initiated and extended posteriorly toward the left atrium (Fig. 80-18). The interatrial septum and fossa ovalis are visualized, and an incision is made in the most posterior aspect toward the patient's right (near the pulmonary veins). Thus, sufficient septal tissue remains not only for retraction of the left atrial roof for exposure of the mitral valve, but also for closure of the atrial septum at the end of the procedure. The septal incision is carried inferiorly down to the end of the fossa ovalis. An incision carried any further will essentially become an extended right atriotomy below the inferior vena cava and should be avoided. Superiorly, the incision is extended beyond the fossa ovalis onto the more muscular portion between the left and right atria near the superior vena cava inlet. Anterior retraction on this left atrial septum results in excellent visualization of the mitral valve because the trans-septal incision is closer to the mitral valve than a standard left atriotomy incision. This incision is particularly useful in the setting of biatrial enlargement often seen in mitral stenosis, as well as in reoperative scenarios in which a previous interatrial groove left atriotomy was performed. It is also a useful approach in patients who have had prior aortic valve replacement, as exposure of the anterolateral commissure can be difficult in this

setting. A variation of this trans-septal incision is the extended trans-septal approach whereby the upper portion of the trans-septal incision is extended over the dome of the left atrium.⁷³ This incision provides outstanding exposure, but is more challenging to properly reapproximate.

Left Atrial Dome Approach

Another less used atriotomy is the isolated left atrial dome approach whereby the roof of the left atrium, in between the aorta and superior vena cava, is incised and retracted. Overall, this incision is smaller given space constraints; however, the direct view of the mitral valve is outstanding. Particular care should be taken during closure of this atrial incision, because bleeding from this incision can be somewhat difficult to repair after weaning from cardiopulmonary bypass, because the incision is obscured by the fully distended aorta and superior vena cava. In most of the aforementioned approaches to the mitral valve, a left atrial vent placed via the right superior pulmonary vein can be positioned with the tip in the left inferior pulmonary vein. An additional suction catheter can be placed from the pericardium into the right inferior pulmonary vein. Typically, one or both of these suction catheters will maintain a completely bloodless operative field and allow perfect visualization of the mitral valve. Two extremely rare and unusual approaches to the mitral valve include a transventricular approach performed in the setting of a left ventricular aneurysm repair⁷⁴ and a transaortic approach performed in the setting of aorto-mitral endocarditis.⁷⁵

Open Commissurotomy

Mitral commissurotomy is indicated in patients with pure mitral stenosis with commissural fusion and preserved leaflet mobility (Fig. 80-19). After left atriotomy, the mitral valve is examined to determine suitability for commissurotomy, and a decision must be made regarding whether the leaflets will be sufficiently pliable after commissurotomy to open adequately at a low left atrial pressure. Ideal valves lack chordal fusion and are not calcified; however, mitral commissurotomy can be performed with acceptable results in less than ideally suited valves.⁷⁶ Yet, advanced commissural calcification, subvalvular fusion, and leaflet retraction may be better treated with valve replacement.

Advanced rheumatic changes can complicate identification of the true commissure locations. Retraction of a stay suture placed in the midportion of the anterior leaflet free edge and another placed similarly in the posterior leaflet helps to identify the commissural groove. Commissurotomy is initiated with sharp dissection along this groove toward the annulus and then toward the center of the valve orifice. It is important to leave a 3-mm ridge of tissue at the commissure to prevent iatrogenic mitral regurgitation. In general, chordae are often more fused beneath the posteromedial commissure. When fused chordae are encountered, they should be fenestrated by removing a triangular wedge of tissue. The incision can be extended to divide the papillary muscle longitudinally

FIGURE 80-18 ■ Trans-septal exposure of the mitral valve. **A**, The right atrium is incised and extended posteriorly. **B**, The septum is incised and extended inferiorly down to the end of the fossa ovalis. **C**, Anterior retraction of the septum exposes the mitral valve.

FIGURE 80-19 ■ Open mitral commissurotomy. **A**, Traction on the anterior leaflet delineates the true commissure between the anterior and posterior leaflet. **B**, The fused commissure is incised sharply and extended toward the valve orifice. **C**, The papillary muscle may be split to improve leaflet mobility. **D**, A triangular wedge is removed to fenestrate fused chordae.

to improve mobility. Finally, localized calcium deposits can be removed from the leaflets with a rongeur forceps.

Mitral Valve Repair

Mitral valve repair is the procedure of choice for correcting severe mitral regurgitation.³ Although techniques for repair are numerous, all valve repairs should aim to restore a large surface of leaflet coaptation, preserve leaflet mobility, and restore physiologic annular geometry with a remodeling annuloplasty.¹⁷ Regardless of the techniques being used, a systematic approach to reconstructive surgery should be used that includes a determination of the mechanism of mitral regurgitation via imaging and valve analysis, application of appropriate repair techniques depending on the culprit lesions, and assessment of the repair quality by pressurized saline testing and echocardiography.

Fundamentals of Reconstructive Surgery

Valve Analysis. The mitral valve apparatus should first be carefully examined to confirm the mechanism of regurgitation, evaluate the feasibility of repair, and plan the technical operation. The mitral annulus is inspected to determine the extent of dilation. Segmental valve analysis with a nerve hook can identify areas of leaflet prolapse or restriction.⁷⁷ It should be noted that prolapse of P1 is less common, and the free margin of other valve segments can be compared with P1 to determine severity of prolapse.

FIGURE 80-20 ■ Remodeling annuloplasty ring implantation. **A**, Dilated annulus with leaflet malcoaptation. **B**, Ring selection is based on measurements of the intercommissural distance and the height of the anterior leaflet. **C**, Sutures are placed circumferentially around the annulus and through the ring. **D**, The annuloplasty ring restores the normal physiologic size ratio and shape of the annulus.

Remodeling Ring Annuloplasty. Regardless of the etiology of valve disease, all patients with chronic mitral regurgitation demonstrate some degree of annular dilation and benefit from a remodeling annuloplasty. As discussed previously, the annulus is weakest along the mural segments and thus typically dilates in the anteroposterior dimension. A remodeling ring annuloplasty restores the normal physiologic size ratio and shape of the annulus, and it improves the surface area of leaflet coaptation. In addition, it improves the longevity of the repair by preventing late annular dilation. Although annular support can be achieved with a posterior band or incomplete ring, the ends of this band must be properly secured in the medial and lateral fibrous trigones to prevent late posteriorly directed annular migration and recurrent mitral regurgitation. Thus, a complete ring with full anterior anchoring typically will more assuredly produce annular remodeling. In most scenarios, annuloplasty sutures are placed first and retracted under tension to improve exposure of the mitral leaflets. Leaflet repair is then conducted (specific techniques to follow; categorized by leaflet pathology), and ring sizing and implantation are performed.

Appropriate ring sizing is based on the intercommissural distance and the surface area of the anterior leaflet (Fig. 80-20). There is usually a strong correlation between the intercommissural distance and the height of the

anterior leaflet. However, if the free edge of the anterior leaflet extends 2 to 4 mm beyond the inferior edge of the selected sizer, a ring that is one size larger should be selected to prevent the risk of systolic anterior motion of the anterior mitral valve leaflet.⁷⁸ Ring sizing also depends on the leaflet repair technique and the amount of functional posterior leaflet tissue that remains. For example, the ring may need to be sized to the mitral orifice area when repairs with artificial neochordae are used.

Simple sutures should be placed circumferentially around the mitral valve and into the mitral annulus (see Fig. 80-20). When placing sutures within the anterior annulus, care should be taken to avoid inadvertent injury to the aortic valve leaflets by taking shallower bites. Similar care should be taken when placing sutures in the area of the anterolateral commissure to avoid iatrogenic injury to the circumflex coronary artery and aortic leaflets. Exposure of the anterolateral trigone region can be improved by exerting traction on the adjacent suture in the posterior annulus. Stretching the commissure in this fashion facilitates proper suture placement. Sutures are then passed through the selected annuloplasty ring. Since the intercommissural distance is equivalent on the anterior annulus and the ring, sutures should be placed evenly through their corresponding places on the ring. However, as the posterior annulus is usually dilated, the spaces of the sutures within the annulus should be greater than their respective spacing on the ring. The ring is then seated to conform the annulus to the shape and size of the prosthetic ring.

Assessment of Repair. The quality of the repair should be evaluated with a saline test after completion of the leaflet repair and again after ring implantation, but before tying the annuloplasty ring sutures so that the surgeon is still free to make additional changes at each stage if corrections are necessary. While the aortic root is vented, saline is injected into the ventricular cavity to prevent air embolism into the coronary arteries. Once air is removed, the aortic root vent is clamped and saline is injected again into the ventricle at a higher pressure. A symmetrical line of coaptation, parallel to the posterior part of the remodeling ring and at a reasonable distance from the left ventricular outflow tract, indicates a successful repair. Asymmetric coaptation lines reveal residual leaflet prolapse or restriction that requires correction prior to separation from cardiopulmonary bypass. A supplemental “ink test” can be performed to further assess the quality of the repair. The valve closure line is traced with a marking pen after pressurizing the ventricle with saline. Saline is aspirated and the leaflet margins are surveyed. Ideal coaptation depth ranges from 4 to 10 mm. A depth less than 4 mm should be corrected by resection of restrictive secondary chordae, cleft closure, or downsizing the annuloplasty ring because shorter coaptation depths suggest limited repair durability. In contrast, depths greater than 10 mm are worrisome for resultant systolic anterior motion, which may warrant further reduction of the height of the posterior leaflet. All valve repairs should be interrogated thoroughly with transesophageal echocardiography after separation from cardiopulmonary bypass.

Valve Repair in Type I Dysfunction

Mitral regurgitation due to type I dysfunction may be due to two aforementioned lesions. Annular dilation is the most common cause, which should be corrected with a complete rigid or semirigid remodeling annuloplasty (see Fig. 80-19).⁷⁹ Type I valve regurgitation may also be secondary to leaflet perforation, commonly seen in infective endocarditis. The management of patching such a lesion is described in further detail later (see [Considerations in Endocarditis](#)).

Valve Repair in Type II Dysfunction

Posterior Leaflet Prolapse. Resection of the prolapsed area or segment has been the conventional technique for repair of posterior leaflet prolapse. However, various nonresecting leaflet repair techniques aimed at preservation of leaflet tissue are well described and increasingly are being adopted.

Quadrangular Resection with or without Sliding Plasty and Triangular Resection. Regardless of the technique chosen, initial placement of annuloplasty sutures helps lift and expose the valve to facilitate repair. When performing the conventional quadrangular resection (Fig. 80-21), stay sutures are placed around normal chordae to delineate the prolapsed area. The prolapsed segment is excised with perpendicular incisions from the leaflet margin toward the annulus to remove a quadrangular section of leaflet tissue. Plication sutures are placed along the posterior annulus in the area of resection. The free edges of the resection gap are then reapproximated with interrupted polypropylene suture to restore leaflet continuity. When the area of prolapse is less extensive, the prolapsing area can be excised with a triangular resection (Fig. 80-22). The free edges of the resection are then reapproximated with polypropylene suture.

In the setting of excessive posterior leaflet tissue, such as in Barlow's disease, it is critical to reduce the height of the posterior leaflet to avoid systolic anterior motion.⁸⁰ Thus, a sliding leaflet plasty technique is performed after initial quadrangular resection (Fig. 80-23). The P1 and P3 segments are detached from the annulus and the gap between the two scallops is then closed with interrupted sutures, taking narrower bites near the free margin and wider bites closer to the annulus. A sliding plasty may also be necessary when a large portion of the posterior leaflet is removed. Interrupted annular plication sutures also facilitate leaflet reapproximation after sliding plasty. However, note that plication of a large segment of the posterior annulus must be avoided because the circumflex artery may kink.

Posterior Ventricular Anchoring Neochordal Remodeling Repair. Minor drawbacks continue to accompany resectional approaches to mitral repair, including irreversibility of leaflet resection, time-consuming leaflet reapproximation with sliding annuloplasty, monoleaflet function, risk for postrepair systolic anterior motion, and potential for dynamic mitral stenosis. Such disadvantages have led to nonresectional paradigms of valve repair, the majority of which are centered on artificial chordal replacement (see [Artificial Neochordae](#) Section). After

FIGURE 80-21 ■ Posterior leaflet quadrangular resection with annular plication. **A**, The limits of the resection are identified and a quadrangular segment of leaflet tissue is removed. **B-D**, Interrupted annular plication sutures are placed to facilitate gap closure. **E**, The residual defect between P1 and P3 is closed.

less successful attempts with different tissue, Frater and colleagues⁸¹ described the utility of polytetrafluoroethylene (PTFE) for chordal replacement in the setting of diseased or ruptured chordae. Numerous modifications to artificial chordal replacement are well described, including the loop,⁸² loop-in-loop,⁸³ haircut,⁸⁴ and butterfly techniques.⁸⁵ Although neochordal construction circumvents many of the drawbacks of leaflet resection, precise sizing is challenging and maintenance of excess leaflet tissue may risk systolic anterior motion of the mitral valve.

In an effort to develop a mitral valve repair technique that avoids the potential disadvantages of leaflet resection and artificial chordal replacement, while simultaneously facilitating port access approaches by reducing leaflet manipulation and simplifying suture management, we implemented a strategy based on a modified leaflet plication repair.⁸⁶ Single suture imbrication of excess prolapsing leaflet tissue onto the noncoaptation ventricular side of the leaflet effectively creates a smooth coaptation

FIGURE 80-22 ■ Posterior leaflet triangular resection. **A**, Stay sutures are passed around nonelongated chordae at the limits of the prolapsed segment and the limits of resection are identified. **B-D**, After resection, the gap is reapproximated with polypropylene suture.

surface without residual prolapse. This technique, however, carries a theoretical risk of basing the repair on potentially diseased native chordae and the potential for the mobile posterior leaflet to advance anteriorly, risking systolic anterior motion. Therefore, we addressed these concerns by further modifying our technique such that a single PTFE suture is used to anchor, support, and remodel the posterior leaflet posteriorly (Fig. 80-24).⁷²

The prolapsed segment is grasped and retracted into the atrium to expose the left ventricular endomyocardium directly below the leaflet. A CV5 PTFE suture is passed into the myocardium approximately 3 to 4 mm deep and loosely tied. The needles are then passed through the margin of the diseased segment at a width of approximately half of the size of the prolapsed region. An inversion plasty is then performed by grasping the leading edge of the diseased segment and inverting it into the left ventricle. The near-apposing leaflet folds are then approximated in a double running fashion with the same PTFE suture that was used to anchor the prolapsed segment. If necessary, additional tissue can be imbricated into the left ventricle using the second half of the PTFE suture.

Posterior ventricular anchoring is not necessary for repair of all cases of posterior leaflet prolapse. If the burden of excess leaflet tissue is not alarming for systolic anterior motion and the subvalvular apparatus does not appear severely diseased, then an isolated inversion plasty may be successfully performed. However, in the setting

FIGURE 80-23 ■ Posterior leaflet sliding plasty. **A**, After quadrangular resection, the gap between the leaflets is too large to permit direct reapproximation. **B**, P1 and P3 are partially detached from the annulus to permit translocation medially. **C**, P1 and P3 are then reapproximated to the annulus, with greater travel along the annulus than along the leaflet to permit medial translocation. **D** and **E**, The now apposed leaflet remnants are reapproximated with polypropylene suture.

of billowing excess leaflet tissue, multiple torn chordae, or severely elongated chordae, it is prudent to perform a posterior ventricular anchoring repair. This repair minimizes risk for systolic anterior motion and helps to buttress a repair that otherwise would be based on diseased native chordae.

It should be noted that several of the following techniques described for repair of anterior leaflet prolapse can be used on the posterior leaflet, particularly in valves with insufficient leaflet tissue.

Anterior Leaflet Prolapse. Several techniques have been described to correct anterior leaflet prolapse. It is our preference to use chordal techniques instead of resection or papillary muscle techniques. However, these additional repair techniques can maximize the probability of repair.

Triangular Resection. Limited prolapse of the anterior leaflet with excess tissue can be treated with a narrow

triangular resection of the prolapsed area. The free edges are then reapproximated with polypropylene suture.⁸⁸ Of note, large resections of the anterior leaflet greatly reduce coaptation area and increase risk for failure. As such, resections of the anterior leaflet should be small (no greater than 10% of the leaflet surface area).

Chordal Transposition. In the absence of normal secondary anterior leaflet chordae, a posterior leaflet chordal transposition may be performed (Fig. 80-25). This procedure is predicated on the presence of normal marginal posterior leaflet chordae opposite the segment of anterior leaflet prolapse. The segment of the posterior leaflet facing the area of anterior leaflet prolapse is identified. A 3-mm-wide strip of posterior leaflet tissue along the leaflet margin is mobilized with supporting chordae. The width of the strip should approximate the width of the prolapsing area. The papillary muscle to which the chordae are attached is mobilized toward the area of anterior leaflet prolapse by splitting. The posterior leaflet strip is then attached to the free edge of the prolapsing segment. The defect at the posterior leaflet donor site is then closed with interrupted polypropylene sutures.⁷⁸ The primary advantage of this technique is that the difficulty surrounding artificial chordoplasty relating to papillary muscle fixation, neochordal length measurement, and tying is eliminated.

Artificial Neochordae. Artificial chordoplasty is particularly useful when the number of normal chordae is inadequate. The primary difficulty surrounding artificial chordoplasty is adjusting the distance between the tip of the papillary muscle and the prolapsing leaflet edge to the precise length needed. Furthermore, fixing the PTFE suture at the correct length is challenging because the slippery nature of PTFE suture causes knots to slide significantly. Lastly, with suboptimal exposure, visualization of and chordal implantation into the papillary muscles can be challenging. In fact, a multitude of techniques has been proposed to tackle these obstacles.^{78,82,89,90}

In the majority of patients, an adjacent normal, non-prolapsing segment of either the anterior or posterior leaflet provides a reference point for the correct plane of leaflet apposition. The appropriate distance is measured between the correct plane of apposition of a nonprolapsing segment and its corresponding papillary muscle with a measuring device or echocardiography. In the “loop” technique (Fig. 80-26),⁸² using a caliper or measuring device as a template, a PTFE neochord loop is fashioned to this premeasured length by tying a knot over a pledget at the required distance. Each end of the suture is passed again through the pledget twice to stabilize the knot position. The needles are then passed anterior to posterior on the respective papillary muscle and tied over a second pledget. A correct, premeasured PTFE loop is thus secured to the papillary muscle. An additional PTFE suture is then used to fix the premeasured PTFE loop to the prolapsing segment of the mitral leaflet, preferably with the knot facing the ventricular surface. Similar to chordal transfer, multiple artificial neochordae may be required for larger areas of leaflet prolapse, and it is essential that no portion of the leaflet margin greater than 4 mm be left unsupported.⁷⁸

FIGURE 80-24 ■ Posterior ventricular anchoring neochordal repair. **A**, Short- and long-axis drawings depicting degenerative mitral valve disease with posterior leaflet prolapse/flail due to ruptured chordae. **B**, The prolapsed segment is retracted into the left atrium to expose the posterior ventricular wall just beneath the leaflet, and an anchoring CV5 PTFE suture is placed. **C**, The suture is loosely tied and the ends brought through the leading edge of the prolapsed segment. **D**, The margin of the prolapsed segment is inverted into the left ventricle, generating two near-apposing radial folds that are then sutured together. **E**, This eliminates prolapse, yielding a smooth broad coaptation surface. (From Woo YJ, MacArthur JW: Posterior ventricular anchoring neochordal repair of degenerative mitral regurgitation efficiently remodels and repositions posterior leaflet prolapse. *Eur J Cardiothorac Surg* 44:487, 2013.)

Alternatively, a PTFE suture can be passed through the papillary muscle and then through the free margin of the prolapsing segment. Following implantation of the annuloplasty ring, the PTFE suture is tied in the setting of a pressurized ventricle. The knot can then be secured at the appropriate level, where coaptation is restored and the visualized regurgitant flow is eliminated. This free-hand technique is more versatile and less complex, but it requires a degree of judgment and skill for determining the proper chord length and for tying without slipping the knot, thereby overly shortening the neochord.

Double Orifice Edge-to-Edge Repair. Alfieri's edge-to-edge technique effectively creates a double orifice mitral valve and may be used to correct posterior, anterior, or bileaflet prolapse (Fig. 80-27).⁹¹ The prolapsing portion of a leaflet is first identified and then resuspended to the corresponding margin of the opposing leaflet with a figure-of-eight polypropylene suture. The depth of each bite from the leaflet free edge depends on the extent of the leaflet redundancy. For example, in Barlow's disease the desired depth is at least 1 cm, which simultaneously decreases the leaflet height to prevent systolic anterior motion of the mitral valve. When leaflet tissue is thin, additional mattress sutures reinforced with pericardial pledgets can be used to support the suture line. If the prolapsing or flail segment does not involve A2 or P2, the valve will be rendered asymmetric with this repair and the size of the two orifices will differ. The overall mitral valve area is assessed by direct inspection; however, when

in doubt, Hegar dilators can be inserted into each orifice. A total valve area greater than 2.5 cm² is acceptable for average-size patients.⁹²

Commissural Prolapse. Commissural prolapse is effectively treated with resection of the prolapsed area and sliding plasty of the adjacent paracommissural segments (e.g., A1 and P1 sliding plasty for anterolateral commissural prolapse). Additional inverting sutures should be placed in the neocommissure to prevent residual regurgitation. Oftentimes, however, less extensive commissural prolapse can be corrected with a simple inverting suture between the lateral most paracommissural segments. Infrequently, a patient will have commissural prolapse secondary to rupture of a two-headed papillary muscle. In this situation, the prolapse can be corrected with reattachment to the remaining papillary muscle. Furthermore, papillary muscle sliding plasty and shortening are useful options for the correction of extensive commissural and paracommissural prolapse.

Valve Repair in Type IIIa Dysfunction

Repair of type IIIa dysfunction must address leaflet immobility and restriction. Leaflet immobility is primarily related to commissural and chordal fusion. These lesions should be addressed with commissurotomy and chordal fenestration as described previously (see Fig. 80-19).

FIGURE 80-25 ■ Chordal transposition. **A**, The segment of the posterior leaflet facing the area of anterior leaflet prolapse is identified. **B**, A strip of posterior leaflet margin tissue is mobilized with its supporting chordae. The corresponding papillary muscle may be split to facilitate transposition. **C**, The posterior leaflet strip is attached to the margin of the prolapsed area on the anterior leaflet. **D**, The residual defect in the posterior leaflet is closed.

The diastolic restriction of leaflet motion characteristic of type IIIa dysfunction can be corrected with leaflet augmentation (Fig. 80-28). For posterior leaflet augmentation, a transverse incision is made 5 mm from the posterior annulus. This incision facilitates excision of fibrotic secondary chordae, but care should be taken to preserve marginal chordae. Autologous or glutaraldehyde-fixed bovine pericardium is then constructed into an elliptical patch. The patch should be sized to increase the height of the posterior leaflet to 15 to 20 mm, leaving a 2-mm margin on the patch for the suture line. The patch is sewn posteriorly from the midline to the annulus and then anteriorly to the leaflet tissue. To account for the new posterior leaflet size, an annuloplasty ring should be chosen that is one size larger than that recommended by standard sizing techniques. The anterior leaflet can also be augmented in a similar fashion; however, a vertical leaflet incision is commonly used.⁷⁸ The patch is sized to the natural gap created by the leaflet incision. Because the anterior leaflet is augmented, an annuloplasty ring should be chosen that is the true size of the new anterior leaflet.

Valve Repair in Type IIIb Dysfunction

Remodeling annuloplasty with an undersized ring is the standard technique to repair type IIIb dysfunction (see Fig. 80-20).⁷⁹ However, the insertion of an undersized prosthetic ring in a severely dilated annulus can cause excessive tension on the sutures, thereby predisposing to ring dehiscence. One can safeguard against this complication by placing multiple sutures around the annulus that overlap. In ischemic mitral regurgitation, this overlapping is particularly important in the area of the posteromedial commissure and P3 segment. In select

FIGURE 80-26 ■ Artificial chordoplasty using the "loop" technique. **A**, The correct plane of apposition of a nonprolapsing segment and its corresponding papillary muscle with a measuring device. **B**, A polytetrafluoroethylene (PTFE) loop is fashioned to this pre-measured length by tying a knot over a pledget at the required distance. **C**, The needles are then passed anterior to posterior on the respective papillary muscle and tied over a second pledget. An additional PTFE suture is then used to fix the premeasured PTFE loop to the prolapsing segment of the mitral leaflet.

FIGURE 80-27 ■ Double orifice edge-to-edge repair. **A** and **B**, A polypropylene stitch is passed in a figure-of-eight fashion through the midportion of the prolapsing segment (in this case A2) and its opposing nonprolapsing segment (in this case P2) to create a double orifice. **C**, During systole, the valve is no longer regurgitant. **D**, During diastole, the double orifice permits ventricular filling.

FIGURE 80-28 ■ Pericardial patch leaflet augmentation. **A**, A transverse incision is made in the posterior leaflet 5 mm from the annulus. Fibrotic secondary chordae can be excised through the leaflet incision. **B** and **C**, Pericardium is fashioned into an elliptical patch to increase the posterior leaflet height to 15 to 20 mm. The patch is sewn posteriorly to the annulus and then anteriorly to the leaflet tissue.

patients, posterior leaflet patch augmentation and resection of secondary chordae may be necessary to ensure a more durable repair.

Annular Decalcification and Annular Reconstruction

Annular calcification complicates mitral valve surgery. The risks of atrioventricular disruption, paravalvular leak, and valve dehiscence are all increased in this setting. In general, débridement of calcific foci is obligatory before valve repair or replacement. Annular decalcification is executed by separation of the leaflet from the annulus and en bloc removal of calcium deposits.^{25,93,94} Often, annular reconstruction is required to repair localized atrioventricular disruption following calcium excision. Similarly, débridement of annular abscesses in the treatment of infective endocarditis may necessitate annular reconstruction.

David and colleagues⁹⁵⁻⁹⁷ and Carpentier and colleagues²⁵ have described different techniques for mitral annular reconstruction. In David's technique, mitral annular reconstruction is conducted using autologous or glutaraldehyde-fixed bovine pericardium. The posterior annulus is reconstructed with a semicircular pericardial patch. The patch is usually 2 cm wide but must be wide enough to cover the defect. One of the margins of this strip is sutured to the smooth endocardium of the inflow of the left ventricle, and the other margin is sutured to the posterior left atrial wall with a continuous 3-0 polypropylene suture. The detached posterior leaflet is then reattached to the pericardial patch at the level of the original annulus. In patients with complete destruction of the annulus, a circumferential patch is tailored for annular reconstruction. An annuloplasty ring is then secured to the pericardial patch. Similar techniques use felt.⁹⁴

In Carpentier's technique (Fig. 80-29), the mitral annulus is reconstructed with figure-of-eight atrioventricular mattress sutures to minimize use of foreign material. Braided 2-0 suture is first passed through the atrial edge and then through the ventricular edge, avoiding injury to the circumflex vessels. The suture is passed again in the same fashion and then upward through the atrial tissue to maintain all suture on the atrial side. Ventricular passes should be at least 1 cm wide and involve one third of the thickness of the ventricle to incorporate any fibrous tissue possible. Closure of the atrioventricular junction is facilitated by downward displacement of the atrial edge with forceps. Not only do the figure-of-eight sutures reduce the size of the annulus, but they also displace the surrounding fat and circumflex vessels away from the reconstructed annulus. The free ends of the figure-of-eight mattress sutures are maintained for later insertion of a remodeling annuloplasty ring. The neoatrioventricular junction is further buttressed with a running polyester suture along the line of closure.

Considerations in Endocarditis

The primary goal of any surgery for endocarditis is complete débridement of all infected and necrotic tissue. The

FIGURE 80-29 ■ Annular reconstruction using Carpentier's technique. **A**, Annular débridement results in a defect necessitating reconstruction. A braided 2-0 suture is first passed through the atrial edge and then through the ventricular edge of the defect. **B**, The suture is passed again in the same fashion and then upward through the atrial tissue. Closure of the atrioventricular junction is facilitated by downward displacement of the atrial edge with forceps. **C**, A running suture line further strengthens the neoatrioventricular junction. **D**, The posterior leaflet is reattached to the reconstructed annulus with a running suture. **E**, The free ends of the figure-of-eight mattress sutures are used for annuloplasty ring insertion. (From Carpentier A, Adams DH, Filsoufi F: *Carpentier's reconstructive valve surgery*, St. Louis, 2010, Elsevier.)

feasibility of mitral valve repair depends on the extent of normal tissue remaining after débridement. Extensive leaflet involvement or subvalvular destruction precludes valve repair. However, valve repair is achievable in a majority of cases provided sufficient tissue remains for reconstruction.⁹⁸⁻¹⁰¹ Mitral regurgitation resulting from localized leaflet perforation (typically the anterior leaflet) is amenable to patch repair with autologous pericardium. To address more extensive valve destruction, surgical reconstruction should integrate the many aforementioned techniques in a lesion-specific approach. Although the implantation of a prosthetic ring remains controversial, in the setting of a dilated annulus, a remodeling annuloplasty ring should be implanted routinely.

Systolic Anterior Motion of the Anterior Leaflet

Systolic anterior motion of the mitral valve is a complication after valve repair that results from a discrepancy between the amount of leaflet tissue and the mitral valve orifice area (Fig. 80-30).¹⁰² Effectively, the plane of coaptation is displaced too anteriorly. It is most frequently observed after valve reconstruction when there is excess posterior leaflet tissue and/or an inappropriately undersized annuloplasty ring. It can also result when there is excess anterior mobility of the posterior leaflet, which can occur when artificial chordae are too long. Consequently, the anterior leaflet is displaced toward the left ventricular outflow tract causing both obstruction and late systolic mitral regurgitation. In most instances, systolic anterior motion of the anterior leaflet may be treated non-operatively. Ventricular underfilling is corrected by increasing preload with volume, raising afterload with pure alpha agonists, and slowing the heart rate to increase diastolic duration. Ventricular hypercontractility is addressed by suspending administration of inotropes. In addition, in the setting of asynchrony, ventricular filling

is augmented by atrioventricular pacing. With these maneuvers, most postrepair systolic anterior motion will resolve, and moderate residual ventriculoaortic gradients (<30 mm Hg) usually normalize in weeks to months from left ventricular outflow tract remodeling.¹⁰³

When systolic anterior motion is irreversible, the repair must be re-addressed, and various measures are enacted depending on the causative factor. Chordal length is corrected if believed to be too long. If the posterior leaflet is too tall, excess posterior leaflet tissue is removed with an ovoid leaflet resection at the base of the posterior leaflet. Thus, the height of the posterior leaflet is reduced and the coaptation zone is moved posteriorly. A posterior anchoring neochord can also be inserted. If systolic anterior motion is due to an undersized annuloplasty ring, the ring should be replaced with a larger ring that is appropriately sized to the anterior leaflet.¹⁰⁴

Mitral Valve Replacement

Mitral valve replacement should be performed in patients in whom mitral valve repair is not suitable (e.g., extensive valve destruction from endocarditis, severe leaflet calcification and fibrosis from rheumatic heart disease, or select patients with ischemic cardiomyopathy).⁷⁹ When possible, chordal-sparing mitral valve replacement is the preferred technique because left ventricular function is better preserved (Fig. 80-31).^{105,106}

Typically, the posterior leaflet is left intact and the tissue is used to better support valve replacement sutures. In addition, this strategy automatically preserves the posterior subvalvular apparatus. In contrast, the anterior leaflet must be transferred if it is to be retained. Otherwise, it will be displaced into the left ventricular outflow tract by the valve prosthesis and obstruct outflow. In certain settings (e.g., highly fibrotic, stenotic valve) the anterior leaflet may need to be completely resected. However, whenever possible, the anterior leaflet and its

FIGURE 80-30 ■ Systolic anterior motion of the mitral valve and the issue of excess tissue. **A**, Dynamic left ventricular outflow tract obstruction from anterior displacement of the zone of coaptation. **B**, Correction by bringing the coaptation zone posteriorly using shorter artificial chordae. **C**, Correction by moving the coaptation zone posteriorly with a sliding plasty to lower the height of the posterior leaflet. **AB**, Height of the posterior leaflet; **B**, free margin of the posterior leaflet; **BC**, length of the chordae. (From Perier P, Hohenberger W, Lakew F, et al: Toward a new paradigm for the reconstruction of posterior leaflet prolapse: midterm results of the “respect rather than resect” approach. *Ann Thorac Surg* 86:722, 2008.)

FIGURE 80-31 ■ Chordal-sparing mitral valve replacement. **A**, The anterior leaflet of the mitral valve is detached from the annulus from commissure to commissure. The anterior leaflet chordae can then be spared in two ways: **(B)** excision of the central portion of the leaflet and tacking the remaining segments to their respective 3- and 9-o'clock positions, or **(C)** direct attachment of the anterior leaflet to the posterior annulus from the 5- to 7-o'clock positions. **D**, Horizontal mattress sutures are placed circumferentially around the annulus (supra-annular, noneverting suture placement shown). **E**, Sutures are passed through the sewing ring of the mitral prosthesis and the valve is secured in position.

chordal apparatus should be preserved. The anterior leaflet is incised in a circumferential manner approximately 3 to 4 mm from the mitral valve annulus, and it is detached from commissure to commissure. The chordae to the anterior leaflet can then be preserved in two different manners. One approach is to excise the central portion of the anterior leaflet (which does not contain chordal attachments) and then suture the remaining anterior leaflet segments at their respective 3- and 9-o'clock positions. Alternatively, the detached anterior

leaflet can be attached directly to the posterior annulus, from the 5- to 7-o'clock positions (see Fig. 80-31). In addition to simplicity and rapidity, this technique offers the additional advantage of buttressing the valve replacement sutures in the posterior annulus, which often is extensively calcified. Thus, the anterior leaflet can effectively double as a broad biologic pledget.

Horizontal mattress mitral valve replacement sutures are placed circumferentially around the annulus in an everting (intra-annular) or noneverting (supra-annular)

fashion (see Fig. 80-31). By surrounding the prosthetic valve sewing ring with everted native mitral valve tissue, the intra-annular technique minimizes any possibility of a paravalvular leak. This technique is especially well suited for mechanical valve replacement because it avoids the possibility of leaflet tissue interfering with the hinge mechanism or the leaflet closure edge of a bileaflet mechanical valve. The disadvantage of the intra-annular technique is that smaller valve prostheses will be implanted compared with prostheses placed using a supra-annular technique. A supra-annular technique facilitates the implantation of much larger prostheses, particularly when using a bioprosthetic valve, because the entire sewing ring is secured in the left atrium rather than within the annulus. This supra-annular location also moves more of the valve out of the left ventricular outflow tract and into the atrium. Disadvantages include difficulty visualizing and properly seating pledgets on the ventricular side of the anterior annulus. Hence, sealing the valve sewing ring down onto the annulus when tying the valve sutures is purely by feel as opposed to direct visualization.

If the anterior annulus is exposed suboptimally, it is helpful to begin the leaflet incision but not completely detach the anterior leaflet from the annulus. The leaflet can then be used as a handle. Applying posterior tension on the partially divided leaflet will bring the anterior annulus further into view and facilitate placement of a mitral valve replacement suture. Once the suture is placed, the anterior mitral leaflet incision can be extended in either direction toward the commissures to allow stepwise placement of the remaining mitral valve replacement sutures in the anterior annulus.

Prosthesis Orientation

With a bioprosthetic valve, the three commissures should be oriented at approximately the 1-, 5-, and 9-o'clock positions, and ideally more toward the 1:30, 5:30, and 9:30 positions. This avoids inadvertent placement of a strut directly in the middle of the left ventricular outflow tract (which rests primarily in between the 10- and 1-o'clock positions). This positioning is slightly less important when using a supra-annular technique, because seating the valve above the annulus results in less valve in the left ventricular outflow tract. Orientation of a bileaflet mechanical valve is not as critical given the relatively low profile of the contemporary hinge guards. However, it is ideal to orient the leaflets in the horizontal plane to ensure that the valve guard is not near the left ventricular outflow tract. Far more important than hinge orientation is confirmation that both leaflets move uninterrupted, and that there is no subvalvular tissue interfering with proper valve closure. If interference is encountered, rotating the valve within the housing can be performed easily using the valve holder. Rotation will usually address the issue by repositioning the closing mechanism away from the area of tissue impingement. If interference persists, the culprit tissue can be resected through the valve or retracted away from the valve with a nonpledgeted suture.

A catheter or vent may be placed through the mitral prosthesis to provide left ventricular decompression by

maintaining the mitral prosthetic valve incompetent. The atriotomy is then closed in standard fashion.

Prosthesis Selection

Important considerations in prosthesis selection include the requirement of permanent anticoagulation, durability, and, of course, patient preference. Because of the limited durability of bioprosthetic valves (particularly in younger individuals), recipient age and life expectancy help to guide professional society recommendations. In patients without a contraindication to anticoagulation, the ACC and AHA recommend a mechanical prosthesis for those younger than 60 years, a biologic prosthesis for those over age 70 years, and either prosthesis for those between 60 and 70 years.³ Finally, patients that have contraindications to permanent anticoagulation should receive a biologic prosthesis.

In general, patients younger than 60 years of age at the time of prosthesis implantation have a higher incidence of primary structural valve degeneration and a reoperation rate as high as 40% in patients 50 years of age, 55% in patients 40 years of age, 75% in patients 30 years of age, and 90% in patients 20 years of age.³ Anticoagulation with warfarin carries an acceptable risk in those younger than 60 years, especially in compliant patients who are carefully monitored. Thus, the balance between durability and risk of thromboembolism or bleeding may favor mechanical prosthesis implantation in those younger than 60 years.³

The likelihood of structural valve degeneration 15 to 20 years after biologic prosthesis implantation in patients older than 70 years is approximately 10%.³ In addition, older patients are at higher risk of bleeding complications from permanent anticoagulation. Because the expected number of remaining life years at 70 years of age in men and women is 13.6 and 15.9 years, respectively, the durability of biologic prostheses typically exceeds life expectancy. Therefore, it is reasonable to implant a biologic prosthesis in those older than 70 years to avoid risks of anticoagulation.³

These recommendations are not absolute and are certainly subject to patient preference. Younger patients might not want to make the lifestyle modifications necessary for permanent anticoagulation. In addition, younger women may prefer a biologic prosthesis to facilitate safer pregnancy. With transcatheter mitral valve replacement technology on the horizon, some younger patients may prefer a bioprosthesis with the prospect of rescue valve-in-valve therapy in the future. Thus, prosthesis selection must be individualized to each patient.

RESULTS

There is an increasing need to minimize adverse outcomes in patients with mitral valve disease, particularly given new professional society guidelines advocating surgery in asymptomatic adults. Operative mortality was the principle outcome measure in the early era of mitral valve surgery. However, as current hospital mortality after valve surgery approaches zero, additional

performance variables such as long-term survival, functional status, and reintervention rates have become increasingly important in evaluating modern surgical treatments of mitral valve disease.

Commissurotomy for Mitral Stenosis

Early Mortality and Late Survival

Although mortality in the early experience with closed mitral commissurotomy was high, contemporary outcomes of mortality after either closed or open commissurotomy are low and similar (less than 0.5%).^{76,107} However, in most institutions, percutaneous balloon commissurotomy has essentially replaced surgical commissurotomy for mitral stenosis. Procedural mortality is near zero, and risk of complications such as severe mitral regurgitation or bleeding requiring urgent operation is low. Furthermore, midterm survival in patients with a good hemodynamic result is satisfactory.

Closed, open, and balloon mitral commissurotomy are not curative procedures. As such, survival increasingly deviates from that of an age-, gender-, and ethnicity-matched population over time (Fig. 80-32).^{76,108,109} It should be noted that death typically results from thromboembolism or reoperation and mitral valve replacement, as opposed to consequences of recurrent or residual mitral stenosis or regurgitation.

Morphologic risk factors identified in the aforementioned scoring systems to assess candidacy for balloon commissurotomy likewise impact the risk of recurrent disease and symptoms. As these risk factors also predict need for reintervention, which is typically valve replacement, it is not surprising that morphologic characteristics also predict survival trends. Survival after redo mitral commissurotomy is also acceptable, with 10- and 15-year survival rates of 83% and 63% being reported. However, 31% of hospital survivors required yet another intervention (typically valve replacement), within an average of 8 years.¹¹⁰

Functional Status

In appropriately selected patients, successful commissurotomy significantly improves cardiovascular symptom burden. In fact, greater than 90% of patients are in NYHA functional class I or II within the first 2 years after surgery.^{109,111,112} Symptom burden is directly related to mitral valve orifice area. Initial relief of symptoms is due to the large increase in mitral valve area afforded by commissurotomy. Various reports demonstrate valve area increases by an average of 0.9 to 2.6 cm² after commissurotomy,^{113,114} with open commissurotomy and balloon valvotomy demonstrating superior results compared with those of closed commissurotomy (Fig. 80-33).^{109,115} However, functional status gradually declines from the continued valvulopathic process with resultant reduction in mitral valve orifice area, regardless of whether rheumatic fever reoccurs (Fig. 80-34).¹¹⁶ This phenomenon is evidenced by the correlation between late postoperative mean mitral orifice area and functional class: 2.0 cm² in patients in class I, 1.7 cm² in class II, and 1.6 cm² in class III.¹¹⁷ Risk factors for poor functional status after mitral commissurotomy include older age, higher preoperative functional class, and greater degrees of valve calcification and leaflet immobility.⁷⁶

Mitral Regurgitation after Commissurotomy

Mitral regurgitation is a clear risk of any commissurotomy procedure. Rates of immediate postprocedure mitral regurgitation vary with type of commissurotomy and are lowest for open commissurotomy (2% to 5% for open,¹⁰⁹ 10% for closed,⁷⁶ and 10% for percutaneous balloon¹¹⁸). Although emergency operation for new mitral regurgitation after commissurotomy is rare, surgery may be necessary within a few months. In addition, severity of mitral regurgitation affects the need for mitral valve replacement and survival, with mild mitral regurgitation demonstrating a minimal effect while more severe grades adversely affect both.⁷⁶

FIGURE 80-32 ■ Survival after surgical mitral commissurotomy. **A**, Actuarial survival analysis with circles representing individual deaths. **B**, Parametric analysis demonstrating the hazard of death after commissurotomy. Dashed dot lines represent an age-, gender-, and race-matched U.S. population. (From Hickey MS, Blackstone EH, Kirklin JW, et al: Outcome probabilities and life history after surgical mitral commissurotomy: implications for balloon commissurotomy. *J Am Coll Cardiol* 17:31, 1991.)

FIGURE 80-33 ■ Mitral valve area after percutaneous balloon (yellow), open (red), and closed (blue) commissurotomy. * $P < 0.001$ compared with baseline. § $P < 0.001$ compared with closed commissurotomy. (From Ben Farhat M, Ayari F, Maatouk F, et al: Percutaneous balloon versus surgical closed and open mitral commissurotomy: seven-year follow-up results of a randomized trial. *Circulation* 97:248, 1998.)

FIGURE 80-34 ■ Functional status after surgical commissurotomy in relation to time since the initial surgery. Note the declining percentage of patients in New York Heart Association class I. In addition, the percentage of patients undergoing mitral valve replacement greatly increases over time. Numbers in parentheses along the x-axis are numbers of patients at each follow-up interval. (From Hickey MS, Blackstone EH, Kirklin JW, et al: Outcome probabilities and life history after surgical mitral commissurotomy: implications for balloon commissurotomy. *J Am Coll Cardiol* 17:34, 1991.)

Reintervention

Because mitral commissurotomy is not a curative procedure, most patients that undergo this procedure require subsequent procedures at some time postoperatively. Most often the subsequent procedure is a mitral valve replacement because worsening leaflet mobility and calcification, as well as progressive subvalvular pathology preclude successful redo commissurotomy. After surgical commissurotomy, valve replacement is performed in approximately 20% of patients within 10 years and 50% within 20 years (see Fig. 80-34).⁷⁶ Similar results are noted in the current era of percutaneous balloon valvotomy, with 60% of patients undergoing repeat intervention within 20 years of the index procedure (76%

FIGURE 80-35 ■ Comparison of overall survival after mitral valve repair or replacement. The purple dashed dot line represents expected survival of the general population, which is similar to survival after valve repair. (From Enriquez-Sarano M, Schaff HV, Orszulak TA, et al: Valve repair improves the outcome of surgery for mitral regurgitation. A multivariate analysis. *Circulation* 91:1022–1028, 1995.)

valve replacement and 24% repeat balloon valvotomy).¹¹⁹ Risk factors for mitral valve replacement after commissurotomy include smaller precommissurotomy valve area, greater leaflet immobility and calcification, greater postprocedure mitral regurgitation, and older age.^{76,119}

Valve Repair for Mitral Regurgitation

Early Mortality and Late Survival

Hospital mortality after isolated mitral valve repair for nonischemic mitral regurgitation is very low. In an analysis of more than 40,000 patients in the Society of Thoracic Surgeons Adult Cardiac Surgery Database, hospital mortality was 1.4% for patients who underwent isolated mitral valve repair between 2007 and 2010.¹²⁰ Furthermore, reference centers have reported hospital mortality rates after mitral valve repair that approach zero.^{63,65,121–125}

Survival over time, inclusive of hospital mortality, of patients with mitral regurgitation who undergo mitral valve repair with or without concomitant procedures is generally better than that of patients undergoing replacement (with the exception of ischemic mitral regurgitation⁷⁹). Contemporary survival data are similar across most centers, with 10-year survival after repair ranging from 68% to 94%,^{63,65,122,126–129} and 20-year survival approaching 50%.^{126,127,130} Variability in survival between reports and improved survival after repair compared with replacement is only partly attributed to the difference in baseline risk profiles of each study population. In the Mayo Clinic experience,^{128,129} operative mortality was 2.6% for mitral repair compared to 10.3% for replacement ($P = 0.002$), and after valve repair late survival (in operative survivors) at 10 years was 69% compared to 58% after replacement ($P = 0.018$). Furthermore, late survival after valve repair did not differ from the expected survival of the general population (Fig. 80-35); however, the two groups differed in their degree of preoperative heart failure and incidence of atrial arrhythmias. To mitigate treatment allocation bias, a number of recent studies have used propensity-score matching to compare outcomes of mitral valve repair and replacement, all of which

corroborate the survival advantage conferred by mitral repair, including in the elderly.¹³¹⁻¹³⁴

Congestive heart failure owing to left ventricular dysfunction is the most common cause of late death after mitral valve repair, and it is best predicted by preoperative left ventricular dysfunction.¹³⁵ Many other variables, such as preoperative symptom burden, cause of valve disease (Fig. 80-36), and age also significantly affect survival.^{43,130,136,137}

Functional Status

After mitral valve repair, symptoms typically resolve and functional capacity is excellent; greater than 90% of surviving patients are reported to be in NYHA functional class I or II 20 years after surgery.^{126,127,137}

Left Ventricular Dysfunction and Remodeling

Beneficial responses of left ventricular performance to mitral valve repair are largely dependent on proper timing of surgery.^{16,45,135,138} In general, mitral valve repair leads to decreased left ventricular strain, regression of left ventricular mass, and decreased left ventricular volume.¹³⁸⁻¹⁴⁰ In fact, in many patients preoperative left ventricular function is preserved. However, even patients with “normal” systolic function preoperatively (ejection fraction > 60%) may develop postoperative left ventricular dysfunction. Quintana and colleagues¹⁴¹ noted that 18.4% of patients had a postrepair ejection fraction of less than 50% despite having “normal” preoperative ventricular function. This ventricular dysfunction failed to recover over 15 years postoperatively in two thirds of those individuals and conferred a 70% increase in the hazard of late death. Similar to other indices of remodeling, ventricular performance is better preserved or improved after mitral valve repair when left ventricular dilation is less severe preoperatively.^{16,139,141} This evidence

strongly supports earlier intervention in asymptomatic patients with progressive left ventricular enlargement.

Residual and Recurrent Mitral Regurgitation

Failure after repair can be classified into three groups: immediate failure (intraoperatively), early failure (<2 years), and late failure (>2 years). Immediate and early failures are typically related to technique, whereas late failure generally is due to continued progression of the valvulopathic process. Analyses of reoperation for failure of mitral valve repair suggest that repair failures are often procedure-related in degenerative disease (usually immediate and early failure) and valve-related in rheumatic disease (usually late failure).¹⁴²⁻¹⁴⁵

The majority of patients have no residual mitral regurgitation immediately after mitral valve repair. In fact, large series from multiple centers report that only 5% of patients demonstrate mild mitral regurgitation prior to hospital discharge, with the remainder having trace or undetectable regurgitation.^{63,146} Intraoperative valve assessment is critical to detect immediate failure. Such failures often are due to suture dehiscence, interscallop leakage, systolic anterior motion of the anterior leaflet, or inadequate surface of coaptation. An unsatisfactory immediate result should prompt re-exploration of the mitral valve and a repeated attempt at effective correction, because residual mitral regurgitation at the end of surgery is directly associated with a high reoperation rate (Fig. 80-37).^{125,129,147,148}

Early failure is defined as new mitral regurgitation after an initially successful repair. Primary causes include absence of a remodeling annuloplasty ring, ring dehiscence from improper sizing or inadequate suture placement, rupture of repaired chordae, or suture line dehiscence on leaflet tissue. Late failure results from progression of underlying disease and typically manifests as new segmental prolapse in patients with degenerative disease or worsening valve and subvalvular fibrosis in patients with rheumatic disease.

FIGURE 80-36 ■ Overall survival after mitral valve repair stratified by etiology of mitral valve regurgitation. Lines: green, degenerative mitral valve disease; red, rheumatic valve disease; blue, ischemic/nonischemic functional mitral valve disease. FMR, Functional mitral regurgitation. (From DiBardino DJ, ElBardissi AW, McClure RS, et al: Four decades of experience with mitral valve repair: analysis of differential indications, technical evolution, and long-term outcome. *J Thorac Cardiovasc Surg* 139:79, 2010.)

FIGURE 80-37 ■ Reoperation rate after mitral valve repair stratified by the presence of residual mitral regurgitation immediately after repair. MR, Mitral regurgitation. (From Mohty D, Orszulak TA, Schaff HV, et al: Very long-term survival and durability of mitral valve repair for mitral valve prolapse. *Circulation* 104:11-17, 2001.)

Although reoperation rate may underestimate the prevalence of late significant regurgitation, the excellent durability of mitral repair is supported by reports of freedom from reoperation ranging between 80% and 96% at 10- to 20-year follow-up.^{121,125-127,130,149} Although there does not appear to be a definitive relationship between repair technique and recurrent regurgitation, repair failure is clearly influenced by disease etiology and valve lesion (Fig. 80-38). After repair of mitral regurgitation owing to degenerative or rheumatic disease, 20-year freedom from reoperation was 82% and 34%, respectively ($P < 0.001$).¹³⁰ In contrast, greater than 30% of patients randomized to mitral repair with ischemic mitral regurgitation in a multicenter trial demonstrated moderate or severe recurrent regurgitation in just 1 year.⁷⁹

Traditionally, categorization of mitral valves by location of leaflet prolapse (posterior, anterior, or bileaflet) is of prognostic consequence as a number of series document lower repair rates and inferior repair durability for isolated anterior or bileaflet prolapse.^{130,150-153} However, durable repair of anterior leaflet prolapse has improved in the current era, and some report equivalent durability compared to that of posterior leaflet repair.^{154,155} With respect to repair techniques, for complex repairs and those involving the anterior leaflet, chordal replacement is superior to chordal shortening.¹⁵⁶ Yet, a randomized trial of the most common techniques for posterior leaflet prolapse did not reveal an appreciable difference in repair durability between leaflet resection and artificial chordoplasty.¹⁵⁷

Thromboembolic Events

Late thromboembolic complications are uncommon after mitral valve repair, although such patients are rarely anticoagulated for the long term. After an initial high hazard of thromboembolism in the perioperative period, the linearized rates of thromboembolic and bleeding events are as low as 0.2% and 0.1% per patient-year, respectively, over a 20-year period.¹²⁶ David and colleagues¹²⁷ found nearly 90% freedom from thromboembolism within the first 10 years after repair, and greater than 80% freedom after 20 years from the index repair.

Systolic Anterior Motion of the Anterior Leaflet

Systolic anterior motion of the mitral valve is noted immediately postrepair in 5% to 10% of patients with mitral valve prolapse.¹⁵⁸⁻¹⁶⁰ As previously mentioned, this complication that results from anterior displacement of the coaptation zone is limited to patients with degenerative mitral valve disease.¹⁰² However, the incidence of systolic anterior motion appears to have decreased given mechanistic insight and the advent of novel nonresectional leaflet remodeling techniques.^{71,72,161,162} It is important to note that most cases of systolic anterior motion do not require surgical intervention. Grossi and colleagues¹⁵⁸ identified systolic anterior motion in 6.4% of mitral valve repair patients intraoperatively, but all patients were treated medically and gradients resolved in every patient within 1 year.

Infective Endocarditis

Infective endocarditis is extremely rare after mitral valve repair as opposed to replacement. Long-term retrospective studies confirm the low risk of postrepair endocarditis, with 10- to 20-year rates of freedom from endocarditis approaching 100%.^{127,137}

Reoperation

The hazard function of reoperation after mitral valve repair is low and constant, without the rising late hazard phase observed with bioprosthetic valve implantation (Fig. 80-39).¹³⁷ As previously discussed, durability of mitral valve repair is excellent, with freedom from reoperation ranging between 80% and 96% 10- to 20-years after surgery.^{121,125-127,130} Etiology of mitral valve disease, location of leaflet prolapse (posterior vs. anterior), and residual regurgitation at the completion of the initial procedure are the greatest risk factors for recurrent mitral regurgitation and reoperation. However, the type of repair technique appears to have no effect on the prevalence of reoperation.¹⁵⁷ A handful of series have examined reoperations after mitral valve repair. Anyanwu and

FIGURE 80-38 ■ Reoperation after mitral valve repair for (A) degenerative mitral valve disease stratified by location of leaflet prolapse (posterior, blue line; anterior, red line) and (B) rheumatic mitral valve disease. (From DiBardino DJ, ElBardissi AW, McClure RS, et al: Four decades of experience with mitral valve repair: analysis of differential indications, technical evolution, and long-term outcome. *J Thorac Cardiovasc Surg* 139:79–80, 2010.)

FIGURE 80-39 ■ Hazard functions for mitral valve reoperation in patients with mitral regurgitation who underwent mitral valve repair or replacement. (From Sand ME, Naftel DC, Blackstone EH, et al: A comparison of repair and replacement for mitral valve incompetence. *J Thorac Cardiovasc Surg* 94:208–219, 1987.)

colleagues¹⁴⁵ noted that mode of failure was attributable to progression of original disease in 36%, technical failure in 38%, and new disease in 26% of patients. Feasibility of valve re-repair depends on the primary etiology of valve disease and is successfully accomplished in 36% to 85% of patients.^{144,145,163,164} The advantages of mitral repair over replacement appear to persist during reoperation. In an analysis of the Mayo Clinic's experience of reoperative mitral valve surgery, mitral re-repair independently improved survival compared to replacement.¹⁴⁴

Mitral Valve Replacement

Early Mortality and Late Survival

Hospital mortality after isolated mitral valve replacement for mitral valve disease ranges between 2% and 7% in a number of series.^{79,131,165–168} A recent examination of 24,404 patients from the Society of Thoracic Surgeons Adult Cardiac Surgery Database revealed a hospital mortality of 3.8% following valve replacement for any etiology of mitral valve disease.¹⁶⁹ However, in older adults (>65 years) who are eligible for Medicare, operative mortality after isolated mitral valve replacement is higher (8.9%).¹⁷⁰

Ten-year survival after mitral valve replacement is generally between 50% and 60%, and long-term survival is independent of prosthesis type chosen (mechanical or biologic; Fig. 80-40).^{168,171–175} Concomitant procedures, such as coronary bypass or tricuspid annuloplasty, decrease long-term survival compared with that of isolated mitral valve replacement.^{137,165,176} However, it should be noted that published results of mitral valve replacement have improved,^{177,178} likely from the adoption of chordal sparing valve replacement. Preservation of papillary muscles and normal ventricular geometry minimize risk of midventricular rupture¹⁷⁹ and aid in maintenance of early postoperative cardiac output.¹⁸⁰

Early and late survival after reoperative mitral valve replacement is less than after the index mitral valve

FIGURE 80-40 ■ All-cause mortality after mitral valve replacement (MVR) stratified by prosthesis type (biologic versus mechanical) up to 16 years postoperatively. (From Hammermeister K, Sethi GK, Henderson WG, et al: Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: final report of the Veterans Affairs randomized trial. *J Am Coll Cardiol* 36:1152–1158, 2000.)

FIGURE 80-41 ■ Actuarial survival after primary valve replacement, first reoperative valve replacement, and second reoperative valve replacement. The purple dashed line represents survival for an age-, sex-, and race-matched general population. (From Blackstone EH, Kirklin JW: Death and other time-related events after valve replacement. *Circulation* 72:755, 1985.)

replacement (Fig. 80-41).^{175,181} This is likely a result of increased technical difficulty inherent to cardiac reoperation, greater functional disability in reoperative patients, and the fact that prosthetic valve endocarditis is a common indication for reoperation. In the current era, however, hospital mortality after reoperative mitral valve replacement has significantly decreased to under 10%.^{182,183}

The most common cause of early and late death after mitral valve replacement is cardiac failure. Modes of late death in operative survivors not owing to cardiac failure include thromboembolism, anticoagulant precipitated hemorrhage, and endocarditis. Unlike patients with acquired aortic valve disease, lethal arrhythmias rarely cause sudden death in patients after mitral valve replacement. Risk factors for premature death include older age (particularly >75 years), left ventricular enlargement and dysfunction, left atrial enlargement, ischemic

cardiomyopathy, significant tricuspid valve disease, severe preoperative functional disability, and failure to preserve the subvalvular apparatus during replacement.¹⁸²

Functional Status

In most patients (>90%), symptoms improve to NYHA functional class II or better. However, patients with more severe chronic disability preoperatively are less likely to gain as much functional improvement. In fact, only half of patients with chronic severe preoperative disability return to NYHA class I after surgery, thereby suggesting that such patients probably harbor a secondary irreversible ventricular cardiomyopathy.

Left Ventricular Dysfunction and Remodeling

In the current era, beneficial responses of ventricular performance are similar to that of repair, though less significant, and largely depend on timing of surgery. Historically, after valve replacement for chronic mitral regurgitation, ejection fraction is at least transiently lower than preoperative values.¹⁸⁴ Although slightly reduced, ejection fraction typically remains within the range of normal when preoperative left ventricular dilation is limited (end-systolic dimension < 5 cm or end-diastolic dimension < 7 cm). When preoperative left ventricular enlargement is severe (end-systolic dimension > 5 cm or end-diastolic dimension > 7 cm), ejection fraction is significantly reduced postoperatively and in some patients may decline even further over time.¹⁸⁴ Ventricular performance and remodeling were significantly improved with the advent of chordal sparing mitral valve replacement. Maintenance of valvular-ventricular interaction preserves systolic performance and leads to beneficial reductions in left ventricular volume and wall stress.^{105,185-187} This has translated into improved survival and global left ventricular function at early and later time points.^{188,189}

Thromboembolic Events

Thromboembolism is one of the more common complications of mitral prostheses, but the incidence is somewhat less in patients with biologic valves (Table 80-5).¹⁹⁰ The incidence of thromboembolism in currently available bileaflet and tilting-disk valves is 1.5% to 2.0% per patient-year. Risk is higher in patients with a large left atrium, intra-atrial clot, or chronic atrial fibrillation. Maintenance of life-long therapeutic anticoagulation, typically with warfarin, is the most important factor influencing the rate of thromboembolism in patients with a mechanical mitral prosthesis. Alternatively, warfarin therapy for 3 months postoperatively and aspirin indefinitely are as effective as long-term warfarin therapy in patients with a biologic mitral prosthesis.¹⁹⁰

Acute Valve Thrombosis

Acute thrombosis of a mitral prosthesis occurs more frequently with a mechanical device than a biologic valve.¹⁹⁰

This complication occurs almost exclusively in the setting of suboptimal anticoagulation. Patients usually present acutely and report a short duration of symptoms (1 to 3 days). Echocardiography is diagnostic, but fluoroscopy may also reveal the diagnosis with evidence of restricted leaflet movement. If the patient is not in cardiogenic shock, acute thrombotic occlusion can be treated with thrombolytic agents.^{191,192} Hemodynamic instability warrants emergency operation, and surgical thrombectomy typically achieves a good result.¹⁹³

Hemorrhagic Events from Anticoagulation

Hemorrhage from anticoagulation usually occurs in the gastrointestinal, urogenital, and central nervous systems, and severity is proportional to the INR. The linearized rate of important hemorrhage has declined, and a recent meta-analysis reported rates of 1% to 2% per year (see Table 80-5).¹⁹⁴ This improvement has coincided with hemodynamic improvements of mitral valve prostheses (Table 80-6) that permit less intense anticoagulation goals (INR required for ball-and-cage valves was 3.5 to 4.5 compared to 2.5 to 3.5 for current mechanical prostheses).

Structural Valve Degeneration

Structural valve degeneration is the principle complication of biologic prostheses in the mitral position. In fact, prosthesis failure accounts for at least two thirds of reoperations in patients with biologic valves.¹⁹⁵ This complication is uncommon in the first 5 years after valve

replacement, but begins to increase thereafter with 15-year freedom from structural valve degeneration in earlier biologic valves nearing 40%.¹⁹⁵⁻¹⁹⁷ Rates of biologic valve failure are higher in the mitral position than in the aortic position, and they are significantly higher in younger individuals (<65 years; Table 80-7).¹⁹⁶ Modes of failure include leaflet tear causing prosthetic mitral regurgitation or leaflet calcification causing prosthetic mitral stenosis. The incidence of structural valve degeneration approaches zero for bileaflet, tilting-disk, and ball-and-cage mechanical valves. Mechanical valve dysfunction owing to chronic ingrowth of tissue and

impairment of the closure mechanism is observed infrequently.

Periprosthetic Leakage

Periprosthetic leakage is an uncommon complication following mitral valve replacement that is generally caused by technical errors. In the current era, the incidence of periprosthetic leakage approaches zero in uninfected patients.¹⁹⁸ Preoperative infective endocarditis and mitral annular calcification increase the risk of this complication. It can cause refractory hemolytic anemia in contrast to the

milder hemolysis observed with some mechanical prostheses, particularly tilting-disk valves.¹⁹⁹ Surgery is indicated in all symptomatic patients and in those with minimal symptoms that require transfusion.²⁰⁰ Alternatively, off-label application of transcatheter septal defect closure devices for these leaks has been successful.

Prosthetic Valve Endocarditis

Prosthetic mitral valve endocarditis is significantly less common than prosthetic valve endocarditis in the aortic position.²⁰¹ However, it remains a serious complication that results in the death of more than half of those affected.^{198,202} Prosthetic valve endocarditis that occurs within 6 months of the primary operation is usually due to contamination in the operating theater. Endocarditis that arises later is generally the result of a new bacteremia.

Prosthetic mitral valve endocarditis that occurs early after surgery greatly increases the risk of dehiscence and death. Broad-spectrum antibiotic therapy should be initiated until sensitivities are identified. In most cases, early prosthetic valve replacement is required. Reoperation should only be deferred if there is a superb response to antibiotic therapy without evidence of peripheral embolization or periprosthetic leakage. Yet, the patient must be followed closely to allow for reoperation if clinical status declines. A similar management strategy applies to prosthetic valve endocarditis that presents over 6 months after surgery. These patients have a better likelihood of responding to medical management compared with those who develop endocarditis earlier. However, medical management is less effective when the culprit organism is more virulent, such as *Staphylococcus*.

Reoperation

Reoperation after mitral valve replacement generally is due to periprosthetic leakage and/or infective endocarditis, as well as structural valve degeneration in the case of biologic prostheses. Actuarial freedom from reoperation 5 and 10 years after valve replacement is approximately 95% and 70% to 85%, respectively. However, the hazard functions for reoperation differ greatly between mechanical and biologic prostheses. Because of structural degeneration, biologic prostheses demonstrate a late rise in risk of reoperation (Fig. 80-42).¹⁷⁵ After reoperation, risk of death and reoperation are higher than after the primary operation, and increase with each successive reoperation (see Fig. 80-41).¹⁷⁵

Minimally Invasive Mitral Valve Surgery

A minimally invasive approach to valve surgery must permit performance of a procedure equal or superior to that of the reference standard median sternotomy approach. Therefore, minimally invasive mitral valve surgery must be as safe, effective, and durable as the traditional “open” approach. In addition to benefits of improved cosmesis, minimally invasive mitral valve surgery was pioneered with the intent of reducing morbidity, postoperative pain, blood loss, hospital length of stay, and time to return to normal activity.

FIGURE 80-42 ■ Hazard of reoperation after mitral valve replacement with a mechanical or biologic prosthesis. While both prosthesis types demonstrate early peaking phases, the hazard function for biologic prostheses also has a late rising phase due to structural valve degeneration. (From Blackstone EH, Kirklin JW: Death and other time-related events after valve replacement. *Circulation* 72:760, 1985.)

Early Mortality and Late Survival

To date, no comparison study has shown a significant difference in operative mortality when comparing minimally invasive mitral valve surgery to that through median sternotomy.^{63,122,203-207} Although reports of initial experiences with port access mitral valve surgery documented mortality rates near 10%,²⁰⁸ recent studies reproducibly demonstrate mortality rates less than 1%, particularly in the case of degenerative mitral valve disease.^{63,122,124,203} Intermediate and long-term results are also encouraging. Propensity score matched comparisons of minimally invasive and sternotomy approaches to mitral valve surgery reveal similar survival up to a decade after surgery.^{63,122,204} In an analysis of 402 well-matched patient pairs at the University of Pennsylvania with mitral regurgitation of any etiology, the 1-, 5-, and 9-year survival was 96%, 96%, and 96%, respectively, after minimally invasive mitral valve repair, and 97%, 92%, and 89%, respectively, following the conventional approach ($P = 0.8$; Fig. 80-43).⁶³

Residual and Recurrent Mitral Regurgitation

Operative approach does not appear to have a significant effect on the likelihood of successful mitral valve repair, with near 100% repair rates achieved for degenerative mitral valve disease through minithoracotomy.⁶³ Durability of the repair is also similar regardless of operative approach. Svensson and colleagues¹²² found that the return of 3+ to 4+ mitral regurgitation after repair at 1 and 5 years were 4% and 5% after minimally invasive surgery, and 6% and 7% after conventional surgery, respectively ($P > 0.1$).¹²²

Postoperative Bleeding and Transfusion

Reductions in postoperative bleeding and transfusion requirements after minimally invasive mitral valve surgery are likely due to smaller incisions and less extensive

FIGURE 80-43 ■ Actuarial survival after mitral valve repair performed via conventional sternotomy or minithoracotomy in a propensity score-matched cohort. *MICS*, Minithoracotomy approach; *OPEN*, median sternotomy approach. (From Goldstone AB, Atluri P, Szeto WY, et al: Minimally invasive approach provides at least equivalent results for surgical correction of mitral regurgitation: a propensity-matched comparison. *J Thorac Cardiovasc Surg* 145:753, 2013.)

mediastinal dissection.* In a propensity score-matched comparison, Svensson and colleagues documented significantly less mediastinal drainage in patients who underwent mitral valve surgery via partial lower sternotomy.¹²² Others have also demonstrated significant associations between less invasive mitral valve surgery and reduced bleeding and transfusion (12% vs. 20% of patients transfused, $P = 0.04$).⁶³ Finally, three separate meta-analyses reported significant reductions in postoperative bleeding and transfusion requirements when surgery was performed via right minithoracotomy or partial lower sternotomy.^{206,207,213} As blood transfusion is associated with an increase in crude risk of major infection, reduction in transfusion requirement may improve both resource utilization and care quality.²¹⁴

Pulmonary Function

The benefit of minimally invasive approaches to mitral valve surgery on pulmonary function remains uncertain. A number of studies, including meta-analyses, documented reductions in the duration of mechanical ventilation when minimally invasive approaches were utilized.[†] Furthermore, in a study from a mitral valve reference center, a significantly higher proportion of patients were extubated in the operating room (18% vs. 6%; $P < 0.0001$) and postoperative FEV1 was higher.¹²² Yet, other experienced centers have not shown such a benefit.^{63,205}

It remains undetermined whether expedited extubation is actually a consequence of enhanced preservation of mechanical chest wall functionality and pain control, or whether different management protocols drive the divergence in duration of mechanical ventilatory support.

Length of Stay

Less invasive platforms for mitral valve surgery also have been advantageous in terms of shortening intensive care unit (ICU) and hospital length of stay.[‡] In fact, more than half of the studies identified in a meta-analysis by Modi and colleagues²⁰⁶ reported significant reductions in the length of hospital stay. Although the overall meta-analysis failed to demonstrate a significant reduction in length of hospital stay, a recent meta-analysis that focused on surgery mainly via minithoracotomy documented significantly shorter ICU and hospital stays (approximately 1 day shorter) in patients that underwent less invasive mitral valve surgery.²⁰⁷ This benefit has also been observed in higher risk patient populations, including older people²¹⁸ and obese people.²¹⁹

Postoperative Pain and Cosmetic Benefits

Outcomes such as postoperative pain and scar cosmesis are difficult to interpret secondary to their inherent subjectivity. In a survey of 187 patients who underwent thoracoscopic assisted mitral valve repair, 93% of patients were highly satisfied with the procedure and reported mild or no postoperative pain, and 99% of patients believed that their scar was aesthetically pleasing.²²⁰ Vleissis and Bolling²²¹ used patients as their own controls when they interviewed 22 patients who underwent reoperative mitral valve surgery via minithoracotomy after previous median sternotomy. All patients in the study believed that their recovery was more rapid and less painful than after their original sternotomy. A more quantitative evaluation of procedural success is time to return to normal activity. A handful of experienced centers have documented that patients return to normal activity an average of 5 weeks earlier after less invasive mitral valve surgery than after mitral valve surgery via median sternotomy.^{61,215}

Cost

In the current era of health care reform and economics, procedural cost and resource utilization have become increasingly important. Prior to cost analysis studies, hospital and ICU length of stay were used as surrogate measures of procedural cost. Subsequently, multiple groups have equated shorter hospital stays after less invasive mitral valve surgery to cost savings ranging from 7% to 34%.^{61,64,67} Further economic benefit may stem from lower rehabilitation requirements and lower rates of early rehospitalization.^{61,63} In an in-depth economic analysis of cost differences between minimally invasive and sternotomy approaches to mitral valve surgery, Iribarne and

*References 61, 63, 67, 68, 122, 205, 209-212.

†References 67, 124, 205, 207, 210, 213, 215.

‡References 67, 204, 210, 212, 216, 217.

colleagues²²² concluded that minimally invasive mitral valve surgery was both cost effective and cost saving; minimally invasive operations were associated with average savings of greater than \$9000 per patient.

Robotic Technology

It is important to note that robot-assisted port access mitral valve surgery has become increasingly adopted at certain reference centers. Initial experience with robotic technology has been favorable.^{66,223,224} Experienced robotic surgeons have demonstrated that the standard surgical mitral repair techniques are replicated with robot assistance and allow for safe and effective repair of all types of leaflet prolapse.^{66,223} In addition to the benefit of reduced ICU and hospital stays, postoperative survival and durability of mitral valve repair have consistently and reproducibly been comparable to that of the reference standard approach, median sternotomy.^{66,223}

Risks

Despite the many benefits of minimally invasive mitral valve surgery, meta-analyses demonstrate that patients may incur an increased 30-day risk of stroke (relative risk [RR], 1.79; 95% confidence interval [CI], 1.35-2.38), aortic dissection/injury (RR, 5.68; 95% CI, 1.23-26.17), and groin infection (RR, 5.62; 95% CI, 1.26-25.13).²⁰⁷

Learning Curve

Although there is a growing demand for minimally invasive mitral valve surgery, its adoption has not been as widespread as expected. In an analysis of the Society of

Thoracic Surgeons Adult Cardiac Surgery Database, Gammie and colleagues⁵⁵ found that among centers that perform less invasive valve surgery, the median number of minimally invasive mitral valve surgeries performed was only 3, and robotic surgery was only performed in 7.2% of database contributing institutions.⁵⁵ The limited adoption of less invasive mitral valve surgery is likely in part a consequence of the steep learning curve associated with these platforms, particularly robotic cardiac surgery. Chitwood and colleagues²²⁵ demonstrated that rates of repair failure fell from 7% to 4.5% after the first 100 robotic mitral valve procedures. Suri and colleagues²²⁶ noted significant reductions in operative times following the first 50 robotic cases. Most recently, Holzhey and colleagues²²⁷ analyzed 3895 mitral valve surgeries performed via right minithoracotomy by 17 surgeons. With the aid of cumulative sum sequential probability analysis, they concluded that the typical number of operations to overcome the minimally invasive learning curve was between 75 and 125. In addition, more than one minimally invasive operation per week was necessary to sustain acceptable results.²²⁷ Thus, a true learning curve exists for minimally invasive surgery of the mitral valve, and given the heterogeneity of individual learning curves, good mentoring in the initial phase is critical. However, as minimally invasive surgeons must perform the same technical operation through smaller incisions, aptitude in mitral valve surgery via the conventional approach is recommended before transitioning to endoscopic platforms.

Percutaneous Technology

Catheter-based cardiovascular interventions have proven particularly effective in the treatment of coronary artery

FIGURE 80-44 ■ Differences in rates of freedom from death, mitral valve surgery, or 3+ to 4+ mitral regurgitation between patients who underwent percutaneous repair or conventional mitral valve surgery. Also shown are subgroup analyses for the study cohort. LVEF, Left ventricular ejection fraction; MR, mitral regurgitation. (From Feldman T, Foster E, Glower DD, et al: Percutaneous repair or surgery for mitral regurgitation. *N Engl J Med* 364:1404, 2011.)

disease. Recently, there has been rapid adoption and implementation of percutaneous treatments for structural heart disease, specifically transcatheter aortic valve replacement. Efforts to recreate the complex surgical techniques of mitral valve repair with catheter-based technologies, however, have been less successful. Alfieri's edge-to-edge technique⁹¹ effectively constructs a double-orifice mitral valve by affixing the anterior and posterior leaflets, but in the contemporary era of mitral valve repair, is generally used as a secondary repair modality. The MitraClip (Abbott Vascular, Abbott Park, IL) replicates the edge-to-edge repair, and is the first catheter-based mitral valve repair system approved for use in the United States. However, initial experience with the device demonstrated poor early and late correction of mitral regurgitation in clinical trials.^{228,229} A phase III comparison of the MitraClip with conventional mitral valve surgery, the EVEREST II trial revealed similar safety outcomes between approaches, but the benefit of reduced blood transfusion requirements was offset by limitations of procedural efficacy (Fig. 80-44).²²⁸ Twenty percent of patients randomized to the MitraClip required salvage with mitral valve surgery due to significant residual mitral regurgitation at 1 year,²²⁸ and approximately 25% needed reoperation at 4 years.²²⁹ Regrettably, salvage mitral valve repair was not possible in nearly half of cases, presumably from physiologic leaflet scarring in response to the clip.²²⁹ Thus, the MitraClip should be reserved for inoperable or prohibitively high-risk patients, as "clip first" strategies may ultimately prevent subsequent mitral valve repair in a significant proportion of patients who may have truly benefitted from the reference standard operation. Additional transcatheter therapies are in earlier stages of development, and they reduce mitral regurgitation via annular reduction or neochordal implantation. As is evident in conventional mitral valve repair, perhaps the most effective and durable transcatheter repair strategy will use more than one repair technique and will be tailored to the cause of the mitral regurgitation. Transcatheter mitral valve replacement devices are likewise in early stages of development and investigation.

The Controversy: Prophylaxis?

The Research

The tricuspid valve is often ignored by cardiologists and surgeons because of its unique characteristics. It is frequently called “The Forgotten Valve,” and there still is scant information regarding the effects of tricuspid valve diseases on the prognosis of cardiac patients.^{1,2} With the exception of infective endocarditis, primary isolated lesions of the tricuspid valve are rare. There are just a few reports on isolated congenital, rheumatic, tumoral, or ischemic diseases. Frequently, the prominent effect of other valve diseases minimizes its importance. Located at the entrance of the heart, the tricuspid valve, when diseased, produces symptoms that are primarily extracardiac and often silent. The behavior of the tricuspid valve is closely related to the function of the right ventricle; in most cases, tricuspid regurgitation is secondary to right ventricular failure. It follows the dictates of the mitral

valve; resolution of the mitral valve problem is often followed by improvement in the degree of tricuspid regurgitation. As the right heart is a low-pressure system, it is difficult to evaluate its preoperative importance and to assess the value of different surgical techniques. These characteristics often lead cardiologists and surgeons to ignore the tricuspid valve. However, the developments in diagnostic tools, and echocardiography in particular, have increased the awareness of this valve, which has been called the “Cinderella” of all cardiac valves.³

SURGICAL ANATOMY

Situated at the base of the heart, the tricuspid valve separates the right atrium from the right ventricle.

Traditionally, it has been accepted that the tricuspid valve consists of three very thin leaflets attached to the tricuspid valve annulus.

Tricuspid Valve Annulus

Whereas the base of the anterior and posterior leaflets is attached to the free wall of the right ventricle, the septal leaflet is inserted into the base of the interventricular septum. This line of leaflet attachment, known as the tricuspid valve annulus, is more a landmark than an actual fibrous ring. This absence of an encircling fibrotic structure explains the large changes in the tricuspid valve orifice during the cardiac cycle and its easy dilation in disease. The mobility and size of the tricuspid valve orifice are dependent on the transversely oriented myocardial fibers that surround the atrioventricular valves according to the breaking studies on anatomy and function by Torrent-Guasp and colleagues⁴ and Buckberg and colleagues⁵ over the past 15 years.⁵ Tsakiris and associates⁶ found in a canine model that the size of the tricuspid valve orifice changed continuously during the cardiac cycle. The orifice area contracted (from its maximal diastolic size) by 20% to 30%. Tei and associates⁷ confirmed these findings in humans with echocardiography. Hiro and colleagues⁸ and Jouan and colleagues,⁹ working with Duran, analyzed an ovine model for the changes in the normal tricuspid valve orifice during the cardiac cycle as detected by the changes in distance between ultrasound crystals placed around the line of insertion of the leaflets (Fig. 81-1). The tricuspid valve orifice area expands and contracts twice during the cardiac cycle. Orifice contraction begins during the isovolumic relaxation phase of the cardiac cycle and continues through the first half of diastole. Starting with the beginning of isovolumic contraction, a second contraction occurs during ejection, which reduces the tricuspid valve orifice to its minimum area. This contraction corresponds to closure of the valve completed at the end of isovolumic contraction.

The reduction in orifice perimeter is not uniform. The segment of the annulus corresponding to the septal leaflet shortens by 12%, the anterior segment by 15%, and the posterior segment by 17%.⁸ The dilation of the annulus occurs in the anterior and posterior segments, and the dilation of the septal segment is restricted because of the relationship with the cardiac fibrous skeleton.¹⁰ This narrowing of the tricuspid valve orifice is due not only to contraction of its perimeter but, more important, to changes in the shape of the annulus. During contraction, the orifice becomes more elliptical because of displacement of the anteroposterior commissure toward the septum and the bulging of the septum. As in the mitral valve, the “annulus” is not in a single plane. In fact, the tricuspid valve annulus is saddle shaped, with its horn or pommel corresponding to the area of the antero-septal commissure and its cantle to the midpoint of the base of the posterior leaflet (Fig. 81-2). This saddle shape or hyperbolic paraboloid, well known to architects as an ideal design to reduce building tension, has been shown in the mitral valve to significantly reduce peak leaflet stress.¹¹ Furthermore, the increase in the saddle shape during contraction has a “folding” and reducing effect on

FIGURE 81-1 ■ Changes in the normal tricuspid valve during the cardiac cycle. *Top*, Pressure curves of blood flow in the pulmonary artery (Pulm flow), the right ventricle (RVP), and the pulmonary artery (Pulm P). *Bottom*, Changes in the areas delineated by the ultrasound transducers placed around the tricuspid annulus (Annulus), the tips of the three papillary muscles (PM), and the free edges of the three leaflets (Leaflets) during two cardiac cycles. These recordings allowed the cardiac cycle to be split into diastole, systole, isovolumic contraction (IVC), and isovolumic relaxation (IVR). (Reproduced with permission from Jouan J, Pagel MR, Hiro ME, et al: Further information from a sonometric study of the normal tricuspid valve annulus in sheep: geometric changes during the cardiac cycle. *J Heart Valve Dis* 16:511–518, 2007.)

the normal tricuspid valve orifice. In cases of tricuspid regurgitation, besides an increase of tricuspid valve annulus area, there is an increase in planarity or flattening of the normal annulus, which induces leaflet tethering.¹² Rigid structures, such as stented prostheses and rigid annuloplasty rings, destroy this configuration and are likely to have a negative impact on the function of the right ventricle.

Leaflets

Although the number of tricuspid valve leaflets varies according to author,^{13,14} it is generally accepted that the tricuspid valve consists of three leaflets. These three leaflets are known as *anterior*, *septal*, and *posterior*, and they

A

B

C

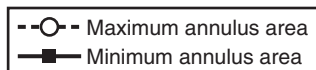

FIGURE 81-2 ■ Geometric changes of the normal tricuspid valve annulus during the cardiac cycle. Orthogonal representations of the tricuspid valve annulus at maximum (dotted line) and minimum (continuous line) area during the cardiac cycle. Circles and squares represent the location of transducers at the mid-point of the bases of the anterior (A), posterior (P), and septal (S) leaflets and at the anteroposterior (A-P), anteroseptal (A-S), and posteroseptal (P-S) commissures. Two relative maxima can be noted in the x-z (B) and y-z (C) planes. P and A-S represent the pommel and the cantle of the tricuspid valve's saddle shape. The representation of the x-y plane is shown in A. (Reproduced with permission from Jouan J, Pagel MR, Hiro ME, et al: Further information from a sonometric study of the normal tricuspid valve annulus in sheep: geometric changes during the cardiac cycle. *J Heart Valve Dis* 16:511–518, 2007.)

C

FIGURE 81-3 ■ Atrial view of the normal (A), stenotic (B), and insufficient (C) tricuspid valve. AV, Atrioventricular. (Reproduced with permission from Duran CMG: Duran ring annuloplasty of the tricuspid valve. *Oper Tech Thorac Cardiovasc Surg* 8:201–212, 2003.)

are separated by three clefts or commissures named *anteroseptal*, *anteromedial*, and *posteroseptal* (Fig. 81-3A). These clefts do not reach the annulus but delineate small “commissural leaflets.” This is an important surgical point because in cases of fused commissures, their incision should not extend all the way to the annulus; doing so destroys the commissural leaflets. The largest leaflet is the anterior, followed by the posterior, with the septal being the smallest. The excursion of each leaflet (defined as the angle between leaflet free edge and the plane of the annulus) is different.⁹ The excursion of the septal leaflet is significantly smaller than that of the other leaflets. This normal, smaller septal excursion might explain the finding at surgery of a septal leaflet plastered against the septum. This finding, often seen in cases of functional regurgitation, is a sign of severity and is a predictor of a poor result after repair.

Chordae Tendineae and Papillary Muscles

The leaflets are held down by marginal and basal chords that arise from three papillary muscle groups. The

marginal chords are inserted into the leaflets free margin, and the basal chords are inserted into the ventricular surface of the leaflets. Elongation or rupture of the marginal chords results in leaflet prolapse. The basal chords of the tricuspid valve, although far less prominent than the mitral valve basal chords, probably play a similar role in maintaining valvular and ventricular geometry. In most tricuspid valve cases, three papillary muscle groups are found and can be identified as anterior, posterior, and septal. Whereas the anterior and posterior muscles are virtually always present, the septal muscle might be absent in 20% of patients. The anterior papillary muscle is the longest; it most often has a single head and sustains the largest number of chordae.^{15,16} Elegant anatomic studies by Victor and Nayak in hearts harvested at random confirm that every heart has a unique chordal configuration.¹⁷

Terminology

New surgical techniques demand deeper knowledge of the anatomy of the region and, consequently, more precise terminology. A common set of anatomic definitions is needed to report precise preoperative and postoperative echocardiographic information important to both the echocardiographer and the surgeon. Aiming to standardize all anatomic findings, Kumar and colleagues¹⁸ developed a detailed tricuspid valve terminology that parallels previously described mitral valve nomenclature. Although it is based on a surgical, atrial view of the valve, their terminology encompasses all three elements of the tricuspid valve apparatus (i.e., leaflets, chords, and papillary muscles).¹⁶

This alphanumeric system is based on the three papillary muscle groups as defined by the numerals 1 for the antero-septal, 2 for the postero-septal, and 3 for the antero-posterior groups of muscles. Each leaflet is identified with the initial letter of its traditional name: *S*, septal; *A*, anterior; and *P*, posterior. Because the lesion does not often affect the whole leaflet or is limited to the chordae, each leaflet is divided into two areas identified by the papillary origin of the corresponding chords. For instance, the septal leaflet (*S*) is divided into two halves (*S*1 and *S*2), identified by the chords that originate from the antero-septal papillary muscle⁴ or the chords that originate from the postero-septal papillary muscle.⁶ The commissures (*C*) are identified by their papillary origin (1, 2, or 3) as *C*1, *C*2, and *C*3. All chords are identified by their papillary origin and leaflet insertion.

Although it is initially confusing, this nomenclature makes it possible to pinpoint the exact location of a lesion and to describe the surgical maneuvers applied. Its use is particularly significant for reporting of chordal disease and chordal replacement.

Anatomic Relationships

The area corresponding to the antero-septal commissure is close to the aortic root noncoronary sinus of Valsalva (Fig. 81-4). This fact has important surgical implications because placement of anchoring sutures for a tricuspid valve prosthetic device can be difficult at this level if a

FIGURE 81-4 ■ Base of the heart showing the anatomic relationships of the tricuspid valve. (Reproduced with permission from Duran CMG: Duran ring annuloplasty of the tricuspid valve. *Oper Tech Thorac Cardiovasc Surg* 8:201–212, 2003.)

stented aortic prosthesis is already present. When a concomitant aortic valve replacement is planned, it is preferable to place the tricuspid valve sutures before undertaking the aortic valve replacement, because tears at this level can be difficult to repair. Of course, the experience and expertise of the operating surgeon finally dictates the operative procedure.

The right coronary artery and sinus run parallel to the segment of the annulus corresponding to the right ventricular free wall. Despite this proximity, injury to these vascular structures in performing a valve replacement or annuloplasty is extremely rare. The ostium of the coronary sinus is situated above the postero-septal commissure. Because of its distance from the conducting system (close to the right trigone), it is safe to place a pursestring suture around the ostium of the coronary sinus to hold a retrograde cardioplegia cannula. This simple anchoring technique described by Martinez-Leon and colleagues¹⁹ more than 25 years ago allows for a reliable positioning of the retrograde cannula.

PATHOPHYSIOLOGY

Tricuspid valve lesions have traditionally been classified into two groups: organic and functional. These classifications have an important effect on both the type of surgery performed and its long-term results. Organic lesions are those in which the valve apparatus is macroscopically abnormal (see Fig. 81-3B). Functional lesions are those in which regurgitation occurs in the presence of an apparently normal tricuspid valve apparatus (see Fig. 81-3C).

A different classification, proposed by Carpentier²⁰ in relation to the pathology of the mitral valve, distinguishes three main types of disease according to the mobility of the tricuspid valve leaflets: type I, normal leaflet motion with annular dilation; type II, increased leaflet motion owing to leaflet prolapse that is secondary to chordal rupture or elongation; and type III, reduced leaflet motion due to leaflet thickening, fused commissures, or leaflet tethering.

BOX 81-1 Causes of Organic Tricuspid Valve Disease

Infective endocarditis
 Rheumatic fever
 Degenerative (myxomatous)
 Traumatic damage
 Postinfarction damage
 Carcinoid
 Appetite-suppressant drugs
 Endocardial fibroelastosis
 Lupus erythematosus
 Tumors (myxoma)
 Mediastinal fibrosis

Organic Tricuspid Valve Disease

A variety of etiologic factors can induce organic regurgitation, but still today the most frequent cause of organic tricuspid valve disease in urban populations is infective endocarditis (Box 81-1). Tricuspid valve endocarditis used to be relatively rare, with an incidence of only 5% to 10% of patients with infective endocarditis; however, its frequency dramatically increased with the spread of intravenous drug abuse,^{21,22} with a peak incidence until early in the beginning of the twenty-first century.²³ In this population, the tricuspid valve usually has no preexisting pathologic change. The lesions vary from isolated vegetations to total destruction of the valve, including the annulus. *Staphylococcus aureus* remains the most common organism found in drug addicts, followed by gram-negative organisms and *Candida* species. Fungal infections are also increasing because of longer periods of invasive monitoring of patients with multiorgan failure in intensive care units.²⁴

In the so-called developing world, rheumatic fever is the primary cause of organic valvular heart disease. Typical lesions show varying degrees of leaflet thickening and (most often) commissural fusion. In severe cases, the thickened leaflets become diaphragm-like, with a central circular orifice (see Fig. 81-3B). The subvalvular apparatus is seldom affected, and calcifications are rare. Although tricuspid valve stenosis is the classic lesion, predominant insufficiency is just as common. In a series of 253 patients with rheumatic heart disease who underwent tricuspid valve surgery, Prabhakar and colleagues²⁵ found that organic involvement was present in 45% of the cases and that 45% of them also had annulus dilation. In a classic study of 100 postmortem hearts with rheumatic disease, Gross and Friedberg²⁶ found microscopic evidence of inflammation in the annulus of all four valves (in the acute rheumatic attack). Rheumatic tricuspid valve disease is always associated with rheumatic mitral valve or mitral-aortic valve lesions. The incidence of chronic rheumatic tricuspid valve disease associated with rheumatic mitral valve disease varies widely, from 6% in an echocardiographic study²⁷ to 33% in an anatomic series²⁸ and 11% in the series of Prabhakar and colleagues²⁵ of 1052 patients undergoing rheumatic valvular surgery. In a Mayo Clinic surgical pathology study of excised tricuspid valves at the time of valve replacement,²⁹

postinflammatory etiology was responsible for 53% of the 363 valves studied. However, this frequency had diminished from 79% during the period from 1963 to 1967 to 24% during 1983 through 1987, reflecting the reduction in the incidence of rheumatic fever in the United States as it happened across Europe. Out of these regions, rheumatic heart disease is still a major epidemiologic problem. Leaflet tears and total or partial avulsion of a papillary muscle head occur after closed chest trauma. They are occasionally diagnosed at surgery and only classified postoperatively as traumatic by the patient, who recalls an old accident when prompted by the surgeon.³⁰⁻³² As imaging has greatly improved in the past two decades, traumatic tricuspid regurgitation is better diagnosed and characterized.³³⁻³⁴

An occasional cause of traumatic tricuspid regurgitation is that induced by the bioprobe during a right myocardial biopsy in transplanted patients. Leaflet tears or chordal avulsion results in severe regurgitation that may require urgent surgery.³⁵⁻³⁷

Degenerative tricuspid regurgitation associated with mitral valve prolapse is being increasingly observed. This double valve lesion is particularly frequent in Marfan syndrome as a manifestation of a fibrilopathy that also involves the aortic valve and ascending aorta. The reported frequency of tricuspid valve involvement among patients with mitral valve myxomatous disease ranges between 21% and 52% at all ages.^{12,38-40} Less common causes include organic tricuspid valve lesions secondary to carcinoid syndrome and appetite-suppressant drugs.⁴¹⁻⁴³ In both cases, the leaflets are encased by a fibrous sheath that reduces their mobility, resulting in stenotic and regurgitant lesions. Other rare causes are listed in Box 81-1.⁴⁴⁻⁵³

Functional Tricuspid Regurgitation

Functional tricuspid insufficiency is understood to be exclusively due to annulus dilation and dysfunction (see Fig. 81-3C). The leaflets, chords, and papillary muscles are otherwise normal. Because of the lack of an anatomic fibrous annulus, the tricuspid valve annulus follows the dilation of the right ventricle. The total perimeter of the normal annulus is approximately 100 to 120 mm. In cases of functional tricuspid regurgitation, the circumference of the annulus can reach 150 to 170 mm.⁵⁴⁻⁵⁵ This annulus dilation is nonhomogeneous. In a postmortem study that included normal controls and hearts with rheumatic or myxomatous tricuspid valve disease, Carpentier and colleagues⁵⁶ showed that the anterior and posterior segments of the annulus dilated far more than the septal portion of the annulus (Fig. 81-5). This report, 40 years ago, formed the basis for all annuloplasties that selectively reduce the whole annulus except at the level of the septum. The role of the papillary muscles in this setting is debatable, although it can be considered a correctable influencing factor.⁵⁷

In congestive heart failure, functional tricuspid regurgitation is a predictor of poor survival⁵⁸ and may be an independent risk factor for the development of cardiac cachexia and protein-losing enteropathy.⁵⁹ Cardiac cachexia continues to be a major risk factor in valvular

FIGURE 81-5 ■ Diagram of the tricuspid valve annulus showing the normal (inner ellipse) and myxomatous (outer ellipse) valve in centimeters. A, anterior leaflet; P, posterior leaflet; S, septal leaflet. (From Carpentier A, Deloche A, Hanania G, et al: Surgical management of acquired tricuspid valve disease. *J Thorac Cardiovasc Surg* 67:55, 1974, with permission from Excerpta Medica, Inc.)

surgery of any origin.⁶⁰ Koelling and colleagues⁶¹ studied a total of 1436 patients with left ventricular systolic dysfunction (ejection fraction < 35%). Mitral regurgitation was moderate in 30% and severe in 19% of patients. Moderate tricuspid regurgitation was present in 23% and severe in 12% of patients. Patients with severe mitral regurgitation were more likely also to have tricuspid regurgitation. The association is clear and it is confirmed that the severity of tricuspid regurgitation is related to the degree of congestive heart failure.⁶²

Advances in echocardiography have revealed another subvalvular mechanism that applies to both mitral and tricuspid functional regurgitations. Originally observed in functional ischemic mitral regurgitations, this mechanism also applies to the ischemic tricuspid valve and most probably to all functional insufficiencies.⁵⁷ Right or left ventricular remodeling induces a lateral displacement of one or more papillary muscles that apically pulls through the basal chords the body of the corresponding leaflet. The leaflet becomes tethered down, losing its coaptation.^{12,63} Tethering in tricuspid valve regurgitation can currently be treated with valve augmentation.^{64,65}

Functional tricuspid regurgitation is an expression of right ventricular failure with a generalized distortion of ventricular geometry. Although annuloplasty can reduce or abolish functional tricuspid regurgitation by reducing the dilated annulus, it does not address the altered subvalvular geometry. Atrioventricular valve regurgitation is therefore influenced by extravalvular factors. Surgery addresses the myocardial component and is aimed at correcting the geometric distortion.⁶⁶

Right ventricular failure and subsequent functional regurgitation are to play a role in the current era of transcatheter valves. If transcatheter valves aim at reducing surgical risks in patients who are deemed inoperable or carrying a risk which is considered too high, the technology and technique should be able to offer better outcomes. In transcatheter repair of mitral regurgitation using the Mitra-Clip (Abbott Vascular, Abbott Park, IL), outcomes are influenced by the residual baseline degree

of tricuspid regurgitation. This has been pointed out recently by Ohno and colleagues,⁶⁷ confirming that 30-day primary safety endpoint was impaired in the GRASP Registry (Getting Reduction of Mitral Insufficiency by Percutaneous Clip Implantation) patients with moderate or severe residual tricuspid endocarditis. Valve regurgitation negatively influenced death and rehospitalization for congestive heart failure at 12 postoperative months; this is in contradistinction with the results after mitral valve surgery. After mitral valve repair or replacement, the risk of progression of tricuspid regurgitation is low, between 3% and 6% up to 5 years postoperatively. The rationale behind a timely operation on the mitral valve encompasses, too, a reduction in progression of tricuspid regurgitation over time.

DIAGNOSIS

The symptoms of the patient with tricuspid valve disease tend to be minimal and overshadowed by the more apparent left-sided symptoms. Because the tricuspid valve is situated at the entrance of the heart, its symptoms are extracardiac. With the exception of advanced cardiomyopathy, it is now uncommon to encounter a patient with the classic symptoms of venous engorgement, such as peripheral edema, hepatomegaly, and ascites. Tricuspid valve disease is mostly silent; the patient mostly complains of asthenia.

The clinical diagnosis of tricuspid valve disease has always been considered difficult. Before the advent of two-dimensional echocardiography⁶⁸ and its application in the operating room through transesophageal probe,⁶⁹ the surgeon used to explore the tricuspid valve digitally through the right atrium and decide whether to treat or to ignore the lesion according to the intensity of the regurgitant jet. This was a common practice three decades ago. This method has been completely abandoned because of its subjectivity and the inability to detect moderate degrees of insufficiency. Right-sided heart catheterization and ventriculography, which were considered the gold standards for the study of all cardiac valves,⁷⁰ have been superseded by two-dimensional color Doppler echocardiography. Because of its noninvasiveness, reliability, and visual impact, two-dimensional Doppler echocardiography is the best tool for determination of the presence, degree, and etiology of tricuspid valve disease. Although transesophageal echocardiography provides invaluable anatomic information at the time of surgery, transthoracic echocardiography remains the most important examination regarding the tricuspid valve. Besides the better window obtained with transthoracic echocardiography, the main reason for its superiority lies in the notorious temporal variability in the degree of tricuspid regurgitation. This is particularly important in functional insufficiencies, in which changes in blood volume secondary to diuretic administration or vascular tone under general anesthesia can severely reduce the degree of regurgitation. Lack of awareness of these facts and exclusive reliance on intraoperative transesophageal echocardiographic examination often result in ignoring significant regurgitations. The advent

of three-dimensional echocardiography is changing the perception of the estimates in tricuspid valve disease, with the understanding of the superiority of two-dimensional echocardiography.

From a surgical point of view, the essential preoperative information includes the following: whether the patient has tricuspid valve disease and whether it is organic, functional, or mixed; quantification of the degree of regurgitation and the direction of the regurgitant jet; pulmonary artery peak and mean pressures; presence and quantification of transvalvular pressure gradients; maximum and minimum tricuspid valve annulus diameter and its systolic shortening; anatomic features of the valve (i.e., leaflet thickness, mobility, billowing of the leaflet body, location of the prolapsing free edge toward the right atrium); and absence of a patent foramen ovale. It is imperative to be aware that underestimation and overestimation of the regurgitant jet area are possible because of changes in gain, filter settings, angle, and distance of the transducer. Experience is required to gain a three-dimensional concept of the direction, location, size, and number of regurgitant jets as the tricuspid annulus is a dynamic multiplanar structure with regional changes.^{71,72} Color Doppler study can even discover minimal regurgitations in 60% to 100% of the normal population, as documented by Yoshida and colleagues⁷³ in normal subjects to set the basis for current understanding. The so-called physiologic regurgitations are useful to evaluate right ventricular and pulmonary pressures.⁷⁴ Contrast echocardiography is a reliable method for detecting tricuspid regurgitation⁷⁵⁻⁷⁷ and a patent foramen ovale.

Semiquantitative evaluation of the severity of tricuspid regurgitation is based on the degree of penetration of the regurgitant jet into the right atrium. A jet that penetrates 2 cm into the right atrium indicates mild regurgitation. A jet that penetrates 3 to 5 cm is considered moderate regurgitation; if it is accompanied by systolic flow reversal of hepatic or caval veins, it is considered severe regurgitation. A more quantitative assessment of the degree of tricuspid regurgitation is performed by the orifice flow acceleration proximal isovelocity surface area radius method. A radius of 1 to 4 mm indicates mild regurgitation; 5 to 8 mm indicates moderate regurgitation; and greater than 9 mm indicates severe regurgitation.⁷⁸⁻⁸⁰ These methods are considered essential in the evaluation of mitral regurgitation, particularly in the intraoperative evaluation of residual regurgitations after repair, and have the same value in the tricuspid valve. Accuracy in determining the actual degree of tricuspid regurgitation is a crucial point in the surgical decision-making process.

Knowledge of the tricuspid valve annulus diameter is important for the surgeon, but its echocardiographic measurement is difficult because the annulus is not circular. As stated, it is a dynamic multiplanar structure with changing regional behavior as clearly depicted by Owais and colleagues.⁷² Small variations in the orientation of the ultrasound beam can provide radically different measurements. The search has been ongoing for a "critical annulus diameter" beyond which the tricuspid valve should not be ignored by the surgeon. Thirty years ago, Ubago and colleagues⁵⁵ suggested 27 mm/m² as the "critical diameter" above which functional regurgitation

always appeared (Fig. 81-6). Using transthoracic echocardiographic examination of 11 consecutive patients with severe clinical tricuspid regurgitation, Come and Riley⁸¹ reported a nonindexed mean diastolic annulus diameter of 51 mm in the four-chamber view and 54 mm in the short-axis view. Among 15 controls, the mean annulus diameter was 34 mm in the four-chamber view and 33 mm in the short-axis view in what is almost a classical contribution. Goldman and colleagues⁷⁵ suggested 30 mm as the cutoff point between absent or mild regurgitation and moderate to severe regurgitation.

A cutoff point must be found beyond which an annuloplasty will fail. Fukuda and associates⁸² in a preoperative and postoperative echocardiographic study of 216 patients with functional tricuspid regurgitation, found that age, tethering height (distance between annulus plane and leaflet coaptation point), and severity of regurgitation were independent parameters predicting residual regurgitation. Preoperative annulus dimension was not associated with outcome of tricuspid valve annuloplasty. In practical terms, it is safe to consider a nonindexed annulus size beyond 40 mm an indication for surgery. When echocardiographic data are not available or are considered unreliable, Dreyfus and colleagues⁸³ suggested using a ruler to measure the maximal stretched orifice from the anteroseptal to anteroposterior commissures. Patients with a dimension greater than or equal to 70 mm (circumference $\pm$ 140 mm, diameter $\pm$ 44 mm) should undergo annuloplasty. All of this forms the basis for the indication for annuloplasty despite some inaccuracy according to the differences among operators.⁸⁴

Preoperative differentiation between organic and functional tricuspid valve disease is also possible and important. Transvalvular gradients, leaflet irregularities, thickening, and doming are clear indications of organic disease. Transvalvular gradients calculated with continuous wave Doppler echocardiography have been shown to correlate well with cardiac catheterization when catheterization was widely used until echocardiography became an established and preferred diagnostic tool.⁸⁵ The normal mean gradient is less than 2 mm Hg, and the end-diastolic gradient is nearly zero. Significant stenosis of the tricuspid valve may be present with a mean gradient of 3 to 5 mm Hg and an end-diastolic gradient of 1 to 3 mm Hg.⁷⁸ Annulus dilation is most often present in both organic and functional lesions, but it is larger in functional regurgitation.^{54,80}

Three-dimensional echocardiography, although preferred for the assessment of the mitral valve, has expanded knowledge of the geometric changes in the normal and diseased tricuspid valve. It is already providing invaluable information on the annulopapillary complex in any valve condition. Accurate assessment is required.^{12,86-88}

INDICATIONS FOR SURGERY

The current consensus is that most diseased tricuspid valves can be repaired easily. Severe lesions are usually treated, but real or erroneously labeled "moderate" lesions are ignored. The problem in the past used to be often related to the absence of a detailed preoperative

FIGURE 81-6 ■ Diagram of the tricuspid valve. **A**, Patients without regurgitation. Both maximal early systolic (D-max) and minimal late end-systolic (D-min) diameters are below the critical diameter (D-crit) of 27 mm/m². **B**, Patients with mild regurgitation. D-max is larger, but D-min is smaller than D-crit. No cusp apposition occurs during early and mid systole. **C**, Patients with severe regurgitation. D-max and D-min are above D-crit. Pansystolic regurgitation. (From Ubago JL, Figueroa A, Ochoteco A, et al: Analysis of the amount of tricuspid valvular annular dilatation required to produce functional tricuspid regurgitation. *Am J Cardiol* 52:157, 1983, with permission from Excerpta Medica, Inc.)

search for tricuspid valve disease. Intraoperative decision making is unreliable unless the lesion is severe. Preoperative transthoracic echocardiography specifically interrogating the tricuspid valve is an absolute requirement. Current trends in three-dimensional echocardiography result in additional preoperative information per the changing behavior of the tricuspid annulus, which is useful in surgical planning.⁸⁹ The value of intraoperative transesophageal echocardiography cannot be neglected.

Can Tricuspid Valve Disease Be Ignored?

In the early phases of valve surgery, the current knowledge indicated that tricuspid regurgitation in the setting of stenotic valve disease could be solved after mitral valve

replacement.⁹⁰ This conservative approach was based on the assumption of postoperative regression of pulmonary hypertension, which would reduce the tricuspid regurgitation. However, early reports like that of Duran and colleagues⁹¹ stressed the effect of residual tricuspid regurgitation on outcomes and warned on the need for early repair of mitral lesions and tricuspid organic disease, when analyzing 150 patients with mitral valve repair and concomitant tricuspid valve disease. Almost 40 years later, there is agreement that residual noncorrected tricuspid regurgitation is associated with suboptimal or poor outcomes.⁹²⁻⁹⁵ These patients with residual uncorrected regurgitation remain at high risk of cardiac death over the follow-up. Reoperative tricuspid patients requiring valve replacement are clinically in poor condition and increased pulmonary hypertension.^{92,95}

Specific Surgical Indications

The severity of the lesion and its reparability are major drivers for the indication for surgery. As stated, the preoperative clinical condition plays a role in the outcomes, too. Severe lesions demand surgical correction regardless of whether repair or replacement will be performed. Moderate lesions should be treated if repair is expected. This principle emphasizes the importance of a precise and accurate preoperative diagnosis. The advances in imaging have allowed better understanding of tricuspid disease and better surgical planning.

Tricuspid Valve Disease Associated with Left-Sided Valvular Lesions

Previous discussion and accumulated data over time support that tricuspid valve disease associated with left-sided valvular lesions should not be ignored, even if it is mild to moderate ($\geq 2+$). It should be treated at the time of the surgery for the other valves.^{92,93,95}

Organic Lesions

Organic lesions should always be treated.^{91,96} In cases of rheumatic multivalvular disease, ignoring the tricuspid valve lesion on the basis of the small gradient present before surgery is dangerous, because it is likely to become significant postoperatively. This is due to the increase in cardiac output after repair of the left-sided lesions. In addition, the persistence of right ventricular preload will further affect the right ventricle and promote further functional regurgitation.

Traumatic Insufficiencies

Traumatic tricuspid insufficiency of any origin has been increasingly diagnosed because of the development in imaging techniques. This can be due to blunt trauma, defibrillator leads, or endomyocardial biopsies among other causes. Traumatic insufficiencies are virtually always amenable to repair. More than 200 brief reports on traumatic tricuspid regurgitation are currently available, and the vast majority report repairs. In chronic cases, the common finding is a leaflet prolapse because of a fibrotic and elongated papillary muscle head. Repair by plication of the elongated head is not technically complex and is usually successful. Acute tears of a leaflet and avulsion of a chord are treated by resection of the unsupported area with reapproximation of its edges followed by selective reduction of the annulus with an annuloplasty. Polytetrafluoroethylene neochords, following experiences in the mitral valve, have also been attempted in addition to regular repair techniques.⁹⁷

Infective Endocarditis

Right-sided infective endocarditis represents less than 10% of the cases of endocarditis.⁹⁸ Surgery for tricuspid valve is usually not the first option in the setting of infective endocarditis, as more than 95% of the cases are cured with antibiotic therapy. However, in patients with

persistent bacteremia or septic shock, septic pulmonary emboli must be operated. The changing spectrum of the complications of the disease take into account a more aggressive disease.⁹⁹ The rate of successful repair is directly related to the degree of valve destruction. Localized lesion may be easily repaired; a destroyed valve requires replacement.

Functional Tricuspid Regurgitation

Functional tricuspid regurgitation must be treated surgically. The initial conduct dictates repair. The current accumulated information confirms the need for surgery in this setting.⁹⁶ It is clear now that residual tricuspid regurgitation is likely to progress over time, as it has been discussed extensively in the literature and previously in this chapter. Tricuspid annuloplasty, per se, is not an incremental risk factor for mortality and can be performed with the heart beating, according to the experience of the surgeon. Despite the ongoing discussions on whether mild to moderate functional regurgitation needs repair, it sounds appropriate today to perform annuloplasty, especially if there is increased pulmonary artery resistance.^{96,100,101} A maximum valve diameter greater than 40 mm is also an additional indication for repair.

Functional Tricuspid Regurgitation after Heart Transplantation

A special subset of patients with functional tricuspid insufficiency are those with regurgitation that appears after heart transplantation. Possible causes of tricuspid regurgitation after transplantation include distortion of tricuspid valve annulus geometry because of the right atrial anastomosis.¹⁰² It has been shown that the change in surgical technique from biatrial to bicaval anastomosis significantly reduces the incidence of immediate regurgitations, size mismatch of the donor heart, and the pericardial cavity.^{103,104} The bicaval technique results in less tricuspid regurgitation early after transplantation, although long-term outcomes do not show differences in functional capacity in relation with the technique. Patients with moderate or severe tricuspid regurgitation at discharge have an increased mortality during the first five postoperative years.¹⁰⁵

Congestive Heart Failure Secondary to Ischemic or Idiopathic Cardiomyopathy with Mitral Valve Regurgitation

Congestive heart failure secondary to ischemic or idiopathic cardiomyopathy with mitral regurgitation is currently treated by “overcorrection” with an “undersizing” ring annuloplasty.^{106,107} This has proved to be effective in improving clinical condition. Tricuspid valve annuloplasty should be added because tricuspid regurgitation is frequently present. It also avoids the progression of annular dilation. Uncorrected tricuspid regurgitation in patients with cardiomyopathy and mitral regurgitation have worse outcomes. As De Bonis and colleagues¹⁰⁸ demonstrated in an elegant contribution with a somewhat large cohort of 91 patients, tricuspid regurgitation

develops because of progression of the disease or failure of repair. Like in other conditions, the degree of residual tricuspid regurgitation and preoperative right ventricular dysfunction are the predictors for late tricuspid regurgitation. This, therefore, supports an aggressive management of tricuspid regurgitation in this setting.

TRICUSPID VALVE SURGERY

Reconstructive techniques and valve prostheses used in the tricuspid valve are similar to those designed for the mitral position. The evolution of the surgery for atrioventricular valves in the past four decades has mostly relied on the Carpentier^{20,109} and Duran^{110,111} techniques as a reference for repair. Replacement devices have been designed for atrioventricular valves with no specific design differences.

Surgical Approaches to the Tricuspid Valve

The approach to the tricuspid valve is easy because of its anatomic location. It can be visualized through a midsternotomy or a right thoracotomy. Unless an isolated tricuspid valve lesion is contemplated, the type of thoracotomy and incision are dictated by the concomitant surgery on the other valves. A standard or a minimally invasive approach can be used safely.¹¹² To establish cardiopulmonary bypass, separate superior and inferior caval and ascending aorta cannulations are used. The right atrial incision is started close to the appendage and directed toward the posterior aspect of the atrium between the right inferior pulmonary vein and the inferior vena cava (Fig. 81-7). This incision minimizes the problem when an accidental tear of the lower extremity of the incision occurs from excessive retraction. The tricuspid valve surgery can be performed easily in the beating heart; however, a number of surgeons prefer cardioplegic arrest. If retrograde cardioplegia is planned, the coronary sinus is located above the posteroseptal commissure and directly cannulated. To ensure maximal distribution of cardioplegia to the whole heart, a pursestring is placed around the coronary ostium. After the retrograde cannula is in place, the pursestring is tightened, the balloon is inflated, and the catheter is pulled outward until it is arrested by the pursestring. This is an old but simple and effective technique to secure the catheter.^{19,113}

In recent years, the principles of a percutaneous approach to the cardiac valves have been applied to the tricuspid valve. It is likely that percutaneous tricuspid valve repair will become widespread because of the accessibility of the valve and the low-pressure environment of the right heart. There is no preferred approach when simultaneous mitral valve surgery is required. A separate biatrial approach is popular, but transeptal approach from the inferior edge of the fossa ovalis or the most complex transatrial septal incision was described by Guiraudon and colleagues.¹¹⁴

FIGURE 81-7 ■ Surgical view of the tricuspid valve through a standard right atriotomy. The “danger” area corresponding to the atrioventricular (AV) node is located near the anterior half of the base of the septal leaflet. Ao, Aortic. (Reproduced with permission from Duran CMG: *Reoperations on the mitral and tricuspid valves*. In Sabiston DC Jr, Stark J, Pacifico A, et al, editors: *Reoperations in cardiac surgery*, New York, 1989, Springer-Verlag, p 346.)

Tricuspid Valve Commissurotomy

The first closed tricuspid valve commissurotomy was performed in 1952 by Charles Bailey.¹¹⁵ Cardiopulmonary bypass brought more precise techniques like open commissurotomy. Percutaneous balloon dilation has replaced closed commissurotomy, which is based on the principle of splitting the commissures through the distending pressure exercised on the leaflets, although the experience in the tricuspid valve is scant.^{116,117} Tricuspid valve balloon dilation is currently reserved for a small number of patients for whom its minimal invasiveness compensates for its mediocre results. In addition, the low pressure in the right cavities minimizes the importance of the frequent residual gradients and iatrogenic regurgitations. Most tricuspid valve lesions are treated surgically in the setting of advanced mitral valve problems that demand surgery.

In performing an open tricuspid valve commissurotomy, the valve should be inspected carefully because, in severe cases, it can appear as a diaphragm with a central circular orifice and fibrotic edges (see Fig. 81-3B). In these extreme cases, it is difficult to identify the commissures. The subvalvular apparatus is often fairly intact; therefore, a conservative procedure is still possible, although the result may be suboptimal. Valve hooks are placed on either side of the commissure to explore the “fan” chordae always present at the commissures. The incision must ensure that its two edges are supported by chordae. It is often easier to start the incision 4 to 5 mm from the annulus rather than at the edge of the fused

FIGURE 81-8 ■ Tricuspid valve commissurotomy. **A**, Opening of the commissure. **B**, Splitting of fused chordae and papillary muscle. **C**, Split papillary muscle. The anterosseptal commissure is opened distal to the free edge to identify the fused chords. **A**, Anterior leaflet; **APM**, anterior papillary muscle; **S**, septal leaflet. leaflets (Fig. 81-8). A better view of the chords will direct the incision toward the free edge. In most cases, two fanlike, thin chords are fused. This incision is then prolonged apically into the papillary muscle for at least 1 cm. The purpose of this essential maneuver is to slow the ongoing fibrotic process and to increase leaflet mobility. At present, these severe forms of commissural fusion are rare in the Western world. Lesser degrees of fusion are frequently present and missed unless the valve is carefully inspected. Often only one or two commissures are affected; the anterosseptal commissure is the most frequently fused. In most cases, a tricuspid annuloplasty must accompany the commissurotomy because of a lack of leaflet tissue or because annular dilation is also present.

Repair Maneuvers

Because most tricuspid valve regurgitations are functional, repair maneuvers other than annuloplasty are less often needed than in mitral valve repair. In acute infective endocarditis, the vegetations must be excised. The vegetation is resected a few millimeters beyond its base in the leaflet. This resection should be in healthy tissue, which is easily identified because of its normal coloration compared with the reddish color of the inflamed area. A triangular resection with its base at the free edge of the leaflet is the best solution. The gap is closed with 5-0 polypropylene sutures. Unless this resection is small, an annuloplasty must follow. Leaflet perforations present in healed endocarditis can be closed with sutures or, if extensive, with a patch of glutaraldehyde-treated autologous pericardium. Fresh autologous pericardium should not be used because it will undergo progressive fibrous retraction. Important tissue destructions can be reconstructed with pericardium supported by polytetrafluoroethylene neochords.⁹⁷

Chordal replacement is not as popular as in the case of the mitral valve. Although papillary muscle and leaflet

FIGURE 81-9 ■ A simple method to determine the correct length of an artificial neochord. The double-ended suture is anchored to the papillary muscle and passed through the leaflet edge, but not tied. After ring annuloplasty, the suture is tied at the level of the annulus (i.e., the level of the annuloplasty). (Reproduced with permission from Duran CMG, Pekar F: Techniques for ensuring the correct length of new mitral chords. *J Heart Valve Dis* 108:727–735, 1994.)

anchoring of the neochord is not a problem, determination of its appropriate length remains intuitive and based on personal experience, which is globally limited when it comes to the tricuspid valve. Following numerous in vitro approaches to this problem, an easy and simple technique was developed by Duran and Pekar.¹¹⁸ A double-ended, 5-0 Gore-Tex (W. L. Gore and Associates, Flagstaff, AZ) suture is anchored to the papillary muscle and the free edge of the prolapsing leaflet (Fig. 81-9) but not tied. After the annuloplasty ring is placed, the two arms of the Gore-Tex suture are tied at the level of the plane of the annuloplasty. Most failures are due to overcorrection, resulting in a neochord that is too short. To simplify this maneuver, the ring holder incorporates two “guide sutures” that traverse the valve orifice at the level of the annuloplasty. After the ring is in place but still attached to the holder, each arm of the artificial chord is passed on either side of the guiding suture and tied (Fig. 81-10) and the holder is removed. In some cases, a patient may need several neochords arising from the same papillary muscle. Implantation of a new neochord is difficult across the annuloplasty. In these cases, a neopapillary muscle is constructed (Fig. 81-11). A loop of approximately 5 mm is made with a double-ended 2-0 Gore-Tex suture. Each arm of the suture is then anchored to the papillary muscle and secured over pledgets. New artificial chords can then be passed easily through the loop (Fig. 81-12). Because of their simplicity, these techniques have transformed mitral and tricuspid valve repair. The edge-to-edge technique, originally described by Alfieri and his group for mitral valve prolapse,¹¹⁹ has also been applied to the tricuspid valve¹²⁰ to configure a double orifice valve. Leaflet suture approximation techniques including the clover technique have been used on a restricted basis.¹²¹

FIGURE 81-10 ■ Intraoperative view: determination of the correct length of the neochord. The annuloplasty ring is already anchored, but the holder is still in place. Each arm of the neochord is placed on either side of the guide and tied at that level. The holder is then removed.

FIGURE 81-11 ■ Neopapillary muscle loop. A 5-mm loop is constructed with 2-0 double-ended Gore-Tex. Each suture's arm is anchored to the medial aspect of the patient's papillary muscle. A number of neochords are passed through the loop.

Tricuspid Valve Annuloplasty

The principle behind tricuspid valve annuloplasty is to selectively reduce the perimeter of the tricuspid valve annulus and, consequently, the size of the tricuspid valve orifice. The lack of leaflet coaptation is compensated by the induced smaller tricuspid valve orifice. The earliest annuloplasties consisted of plication of the annulus at the level of the base of the posterior leaflet. This approach, borrowed from the early mitral valve annuloplasties, was described by Wooller and colleagues¹²² and Kay and colleagues¹²³ (Fig. 81-13). Both have been abandoned

FIGURE 81-12 ■ Multiple neochords anchored by the neopapillary muscle. One loop can sustain all chords corresponding to one papillary muscle. If there is a need to anchor neochords sustained by other papillary muscles, a separate loop must be constructed.

FIGURE 81-13 ■ Tricuspid valve annuloplasty. Posterior annulus plication or Kay procedure. A, Anterior leaflet; P, posterior leaflet; S, septal leaflet. (From Boyd AD, Engelman RM, Isom OW, et al: Tricuspid annuloplasty. Five and one-half years' experience with 78 patients. *J Thorac Cardiovasc Surg* 68:347, 1974, with permission from Excerpta Medica, Inc.)

because of the difficulty in determining the amount of plication necessary and the lack of support for the remaining annulus. Cabrol¹²⁴ and De Vega¹²⁵ independently described a partial encircling suture to narrow the annulus. The extremities of a double suture that runs

FIGURE 81-14 ■ Tricuspid valve annuloplasty. A de Vega semicircular suture annuloplasty. A, Anterior leaflet; CS, coronary sinus; P, posterior leaflet; S, septal leaflet. along the base of the anterior and posterior leaflets are anchored with pledgets at the anteroseptal and postero-septal commissures (Fig. 81-14). The partial pursestring is tied over an obturator of the desired size. This technique has been popular because of its simplicity and low cost. The De Vega suture-based technique has stood the test of time despite it being heavily criticized because of late recurrence of valve incompetence.^{126,127} The description of Carpentier of a measured rigid prosthetic ring that selectively reduces the annulus opened the era of modern mitral and tricuspid valve annuloplasty.¹⁰⁹ The ring has the systolic shape of the tricuspid valve annulus and is open at the level of the anteroseptal commissure to avoid passing the anchoring sutures close to the conduction system.

As the tricuspid annulus is a dynamic structure with continuous changes in size and shape during the cardiac cycle,^{6,7} a totally flexible and complete ring was developed.¹¹¹ The flexible ring was designed to reduce and selectively reinforce the entire mitral or tricuspid valve annulus with minimal interference in the complex function of the atrioventricular valves. The surgical technique for implantation of a tricuspid valve ring is similar for all types of devices.¹²⁸ Selection of the appropriate ring size is based on the length of the septal segment of the annulus (Fig. 81-15). Large U sutures are placed around the annulus and through the ring (Fig. 81-16). In the septal area, the sutures are passed through the base of the septal

FIGURE 81-15 ■ Tricuspid valve flexible ring annuloplasty: determination of the appropriate ring size by use of the septal annuloplasty anchoring sutures. leaflet to avoid damaging the conduction system. The ring is brought down and the sutures are tied, reducing the overall perimeter of the tricuspid valve annulus (Fig. 81-17). Open bands that selectively reduce the posterior mitral annulus have been developed and applied to the

FIGURE 81-17 ■ Tricuspid valve flexible ring annuloplasty: ring in place. The ring sutures have been tied with the ring holder in place, which makes the ring temporarily rigid and therefore avoids plication. (Reproduced with permission from Duran CMG: Duran ring annuloplasty of the tricuspid valve. *Oper Tech Thorac Cardiovasc Surg* 8:201–212, 2003.)

tricuspid valve. In the tricuspid valve, the annulus contention is limited to the base of the anterior and posterior leaflets.¹²⁹ The band designs are based on the assumptions that the intertrigonal distance of the mitral valve and the tricuspid valve septal annulus do not change during the cardiac cycle. However, these areas change continuously in the normal heart¹³⁰ and, more important, also dilate progressively in disease. A partial annuloplasty does not totally protect against further dilation. Although partial annuloplasties are apparently easier to implant than complete rings, they require more expertise (Fig. 81-18).

Tricuspid Valve Replacement

Although the majority of tricuspid valve lesions can be repaired, in some cases the degree of valve destruction is such that it must be excised. The alternatives are excision of the valve without replacement, use of mitral or tricuspid valve homografts, replacement with stented porcine valves or stent-mounted pericardial xenografts, and replacement with a mechanical prosthesis. The epidemic increase in endocarditis caused by drug abuse and the poor rehabilitation of these patients stimulated Arbulu and Holmes¹³¹ to advocate complete excision of the tricuspid valve without replacement. They reported the long-term results of tricuspid valvectomy in 55 patients with mortality of 29% at 13 years after surgery. Although the absence of a tricuspid valve may apparently be well tolerated, the fact that these patients were very young and had normal pulmonary artery pressures must be emphasized.

The expected higher resistance to infection of aortic homografts rekindled an interest in the use of atrioventricular homografts. The first experimental tricuspid

FIGURE 81-18 ■ Tricuspid valve flexible annuloplasties: complete ring versus open band devices. **A**, Ring in place. **B**, Band in place. **C**, Band incorrectly implanted, resulting in a larger tricuspid valve orifice than planned. **D**, Band correctly implanted does not protect against further dilation of the septal annulus. valve replacements with atrioventricular homografts were performed by Robicksek,¹³² who reported his early results in 1954 and used a homologous tricuspid valve and in 1965 by Hubka and coworkers¹³³ who used a mitral valve homograft. These techniques were followed by isolated, intermittent, and mostly unsuccessful clinical cases until 1993, when we reported successful tricuspid valve replacement with a mitral valve homograft²¹ observed for up to 20 months and di Summa and colleagues¹³⁴ reported the use of a fresh tricuspid valve homograft. Despite satisfactory results over 5 years,^{22,135} the applicability is limited as endocarditis of the tricuspid valve is successfully cured with antibiotic therapy in a large proportion of the cases.⁹⁸

In practice, all tricuspid valve replacements use standard mechanical or stented glutaraldehyde-treated porcine valves or stent-mounted pericardial xenografts. The arguments between the proponents of either alternative are based on the problem of the permanent anticoagulation required with a mechanical prosthesis versus the limited durability of the bioprosthesis. In most cases of tricuspid valve replacement, the entire tricuspid valve apparatus should be retained. Interrupted, pledgeted U sutures are passed along the annulus, incorporating the leaflets. Care must be taken to avoid damaging the atrioventricular node with the septal sutures close to the anteroseptal commissure. In this region, the pledgeted U sutures should be passed at the base of the leaflet,

avoiding myocardial tissue. These riff sutures not only increase the holding power of the stitches but also maintain the continuity between the annulus and papillary muscles, which have been shown in the mitral valve to be essential to ventricular function. The controversy on whether a mechanical or a tissue valve is preferable in the tricuspid position is still active and proponents define the need for anticoagulation and good right ventricular function as preoperative indicators for such an implant.¹³⁶

RESULTS

Annuloplasty

The review of the literature has regularly shown inconsistent results. As the tricuspid valve is a low-pressure system, different degrees of incompetence can be acceptable and well tolerated despite suboptimal results. This was highlighted by Duran and colleagues three decades ago in their elegant review of a series of 150 patients with mitral and tricuspid regurgitation who had preoperative and postoperative hemodynamic evaluations at different intervals extending up to 5 years.⁹¹ All patients had mitral valve repair, and 119 had concomitant tricuspid valve repair; in 31 cases, the tricuspid valve lesion was ignored by the surgeon. Independently of whether the tricuspid valve repair was categorized as “good,” “bad,” or “ignored,” 97% of those with a good mitral valve repair were in functional class I or class II. The quality of the mitral valve repair determined the postoperative cardiac index. At that time and because of these data, strongly emphasizing the need for an early repair of left-sided lesions, these authors were able to conclude that functional TI could be ignored only in patients with predictable and significant reduction in pulmonary vascular resistances and that organic disease of the tricuspid valve must be repaired.

During the 1980s, the superiority of repair over replacement became clearly established. It was shown that repair was possible in most cases including organic lesions. The experience of Prabhakar and colleagues²⁵ with the repair of rheumatic organic lesions with over 90% of patients with satisfactory functional results was encouraging at that time. The absence of valve thrombosis, the unnecessary permanent anticoagulation, and a low reoperation rate have reduced valve replacement to the exceptional case in the case of degenerative or functional disease.^{137,138} The experience of Duran with 306 patients, 92 with proactive tricuspid valve surgery generally indicated in healthier patients yielded in-hospital mortality of 7.5% and actuarial survival rate of 77% at 48 months.¹¹⁰ This relatively low survival at an interval shorter than 5 years indicated that these tricuspid patients were in worse condition than expected. The selection process at that time was negatively influenced by the lack of good imaging of the tricuspid valve preoperatively, intraoperatively, and postoperatively.

These findings favored a more aggressive surgical attitude toward the tricuspid valve, and consequently, earlier indications extended into the lower-risk patients. This attitude has been documented over time with different

devices for tricuspid annuloplasty. The recent experience of Ratschiller and colleagues¹³⁹ is confirmation, although the follow-up for specific devices is still short. The experience over four decades with different techniques of annuloplasty with or without rings or bands confirms that, over time, residual stenosis and regurgitation can become a problem that was documented when early studies showed significant gradients in 50% of patients with a De Vega annular reduction and residual or recurrent regurgitation in 41%.¹⁴⁰ The same occurred with the early types of ring, the Carpentier-Edwards rigid ring (Edwards Lifesciences, Irvine, CA; 48% significant gradients, 31% residual or recurrent regurgitation) when analyzed in early studies¹⁴¹ and the Duran flexible ring (Medtronic, Inc., Minneapolis, MN; 31% significant gradients, 30% residual or recurrent regurgitation).⁵⁴ Technical failures over time, such as ring fracture, were not common although documented.¹⁴² Late factors for ring annuloplasty failure were studied by McCarthy and colleagues¹⁴³ in a large series of 790 patients with functional tricuspid insufficiency; residual or recurrent significant regurgitation graded as 3+ to 4+ was detected in 32% of the patients with the Peri-Guard band (Synovis Life Technologies, St. Paul, MN), 28% with the De Vega suture, 18% with the Cosgrove-Edwards band, and 17% with the Carpentier-Edwards rigid ring. On the other hand, tricuspid regurgitation can develop after successful mitral valve repair for functional ischemic regurgitation, as shown by Matsunaga and colleagues.¹⁴⁴ Almost 50% of patients had significant tricuspid regurgitation at the latest follow-up control after myocardial revascularization and reduction mitral annuloplasty.¹⁴⁴ These results suggested that tricuspid valve reduction annuloplasty might not consistently protect against recurrent functional regurgitation. Functional regurgitation of the atrioventricular valves continues to be a problem, the reason being, as it is currently well known, that cardiomyopathy-induced ischemic disease leads to changes in the right and left ventricular geometry. It is unlikely that the myocardial component can be corrected by any type of prosthetic annuloplasty device of any configuration.² Additional controversy between rigid rings and flexible bands is still active. The lack of controlled studies aiming to shed some light is still a limitation; however, a recent best-evidence topic suggests that although there is relatively less risk of ring dehiscence or fracture in the flexible group, with the rigid ring there is a trend toward a more sustainable and stable postoperative regurgitation.¹⁴⁵

Tricuspid Valve Replacement

Almost 60 years is the interval between the earliest documentation of experimental tricuspid valve replacement and today.¹⁴⁶ It would not be fair to state that things have not changed much when discussing the fate of right atrioventricular valve and orifice in the adult. Cardiac surgery has evolved in a way in which, from a primitive surgical conduct, the current trends are signaling toward a global reduction in the access to the heart following the call of technology.¹⁴⁷ However, the replacement of the tricuspid valve continues to be a challenge for the physicians and

surgeons. As it is clear, the preoperative condition of the patient with tricuspid valve disease dictates outcomes, and these patients usually arrive late and in bad shape predominantly because of right heart failure. Some predictors for failure of repair have been identified in recent years,^{83,148} and the ability of surgeons to achieve a satisfactory anatomic and functional result have rendered tricuspid valve replacement an uncommon operation when compared with mitral or aortic valve replacement in the adult setting.

A number of problems with tricuspid valve replacement are notorious. Despite acceptable results in some series with different types of replacement devices over time,¹⁴⁹⁻¹⁵¹ prosthetic valve dysfunction is a well-recognized condition that carries risk of morbidity and mortality in otherwise usually sick patients.¹⁵² Current data have not been able to show the superiority of a specific prosthetic device.¹⁵³ Speculation about outcomes related to specific factors like gender,¹⁵⁴ among others, has not been confirmed due to the lack of robust data over time.

As tricuspid valve repair is achievable in a large proportion of patients, the published series of tricuspid valve replacement include reduced numbers.¹⁵³ Follow-up has always been a problem in medicine, and it is a key tool to assess the effectiveness of any procedure. There is not an agreed definition of what *long-term* means, and it usually remains a subjective interpretation of time frames depending on what the author wants to report. In cardiothoracic surgery, there has always been an interest in reporting over time. As we enter the sixth decade of valve replacement,¹⁵⁵ we are in a position to analyze actual long-term results of procedures performed by our predecessors. This is the case in valve surgery, which is why we are in need of studies that span a long time, diluting the improvements that have occurred in cardiac surgery. Reports with long follow-up, over two decades, include very different tricuspid valve pathologic processes and often include reoperations.¹⁵⁶ Furthermore, only severe tricuspid valve lesions are treated in poor-risk and evolved patients. Moderate lesions are rarely treated with replacement in current times. The reported hospital mortalities varied between 15% and 25%¹⁵⁶⁻¹⁶⁰ and have not substantially improved in the past 20 years. When isolated tricuspid valve replacement was reported, the hospital mortality went up to 39% in the series of Poveda and colleagues,¹⁶¹ which included patients operated on between 1974 and 1993. When the replacement was subsequent to previous open heart surgery, Hornick and associates¹⁶² reported a hospital mortality of 50% in patients operated on between 1985 and 1993. A more recent experience of 34 patients undergoing isolated tricuspid valve surgery after prior left-sided heart surgery between 1980 and 1997 showed a hospital mortality of 8.8%.¹⁶³ However, at 5 years, the event-free actuarial survival was only 41%. Predictors of poor outcome were the age of the patient, number of previous surgeries, preoperative functional class, congestive heart failure, and pulmonary artery pressure.^{161,162} The published late mortalities were close to 50%¹⁵⁷⁻¹⁵⁹ with survivals of 70% at 3 years for Sanfelippo and colleagues,¹⁶⁴ 47% at 10 years for Thorburn and colleagues,¹⁶⁵ and 41% at 8 years

for Kratz and colleagues.¹⁶⁶ In most series that stretch back to the 1970s, insignificant differences in the overall results are found between mechanical and tissue prostheses for tricuspid valve replacement. Recent series, with or without comparison with tricuspid valve repair, confirm the knowledge that tricuspid valve replacement is associated with long-term cardiac death and valve-related events.¹⁶⁷⁻¹⁶⁹

Standard bioprostheses in the mitral and aortic positions are known to fail because of leaflet tears and calcification, with an incidence of about 25% at 10 years after implantation. There is currently important accumulated information supporting that specific model and tissues have good behavior beyond two decades. Bourguignon and colleagues¹⁷⁰ have recently shown that the actual risk of explant at 20 years of the Carpentier-Edwards pericardial xenograft is 25.5% in a series of over 400 patients followed up to 25 years. Good results have also been reported for other bioprosthesis like the Hancock II, with 20-year freedom from reoperation at 41.4% in mitral patients younger and 61.9% in patients older than 60 years. These can be considered good results.¹⁷¹

However, such complications are rare in the low-pressure pulmonary and tricuspid positions in the adult and children.¹⁷² Ohata and colleagues¹⁷³ reported a comparative study of patients with the Carpentier-Edwards pericardial xenograft in the mitral and in the tricuspid positions. The actuarial freedom from structural deterioration and reoperation at 13 years was 78% for the mitral valve versus 100% for the tricuspid valve. Although these findings would favor the tissue valve, several studies do not show significant differences between mechanical valves and bioprostheses. Carrier and associates¹⁷⁴ in 2003 reported a series of 97 patients with tricuspid valve replacement who were observed for up to 25 years. The overall hospital mortality was 17.5%. Because of their acknowledged preference for the bioprostheses, the authors compared two unequal groups of 81 patients with bioprostheses versus 15 patients with a mechanical valve operated on between 1977 and 2002. No significant differences were found in survival and reoperation rates between the groups. The 5-year actuarial survival was 56% in the bioprosthesis group and 60% in the mechanical group. The freedom from reoperation at 5 years was 97% and 91%, respectively. Describing 435 patients in the U.K. Heart Valve Registry, Ratnatunga and colleagues¹⁷⁵ showed similar survival and reoperation rates of patients with biological and mechanical prostheses. Kaplan and associates¹⁷⁶ also reported similar results among 122 patients averaging 35 years of age at the time of tricuspid valve replacement. Although prosthetic thrombosis and pulmonary embolism occurred in 10 patients, the authors recommended the use of low-profile, bileaflet prostheses. Still, the decision regarding the implantation of a mechanical or tissue valve in the tricuspid position has to be individualized. Songur and colleagues¹⁵³ did not find statistically significant differences over the long-term in their series of 132 patients—one of the largest series. The problem of mechanical valve thrombosis was highlighted by Kawano and colleagues,¹⁷⁷ who reported thrombosis in 6 of 23 patients with a St. Jude Medical valve in their contribution of the year 2000.

Historical series had a proportion of patients dying in whom the actual cause of death was unknown. This might have been due to the lack of postmortem examinations, thus leaving doubts regarding eventual thrombosis.¹⁴⁹ Although thrombosis of a bioprosthesis in the tricuspid position is rare, fibrous pannus formation occurs more often. It leads to progressive stenosis requiring reoperation. Kawachi and associates¹⁷⁸ reported a small series of 23 patients who underwent tricuspid valve replacement with a standard Hancock bioprosthesis. All patients were observed for up to 16 years. The actuarial freedom from structural degeneration was 94% at 10 years. This also occurred in mechanical valves, but only brief reports have been made available.¹⁷⁹ The evolution of imaging techniques has allowed for better visualization of the atrial and ventricular aspects of the valves, thus providing better chances of accurate diagnosis. Three-dimensional echocardiography and more recently multidetector computed tomography have improved our ability to assess atrioventricular prosthetic heart valves.¹⁸⁰

It is difficult to confirm at this point in time if tissue valves are superior to mechanical valves for tricuspid valve replacement. The fact is that there are no large series supporting the superiority of one over the other. The series of Songur includes 123 patients and is one of the largest published recently.¹⁵³ Hemodynamics alone might not be the problem.¹⁸¹ The danger of thrombosis and the need for a stringent anticoagulation regimen when a mechanical valve is used versus the satisfactory performance of tissue valves tilt the balance toward the bioprostheses. History describes our inability to appropriately address atrioventricular valve replacement and especially in the tricuspid position there is a need for more anatomic and, consequently, more physiologic new tricuspid valve prostheses. The underlying message is that patients requiring tricuspid valve replacement are in poor condition preoperatively, and this is the major driver for increased risk and mortality.

KNOWLEDGE AND EVIDENCE

Knowledge

It is clear that the controversy still exists. After many years of experience with the surgical treatment of tricuspid valve diseases, some topics still are difficult to handle. The type of disease is a key component in the discussion. In Westernized countries, functional tricuspid regurgitation seems to be the most frequent diagnosis¹⁰⁰ with valvular regurgitation mostly developing after left-sided valve procedure. The question is whether the degree of regurgitation matters¹⁸² or whether the effect on myocardial function will affect survival.¹⁸³ Kammerlander and colleagues¹⁸⁴ recently analyzed a series of 91 patients who underwent left-sided surgery and found that although late survival was worse in patients with tricuspid regurgitation, right ventricular dysfunction was associated with survival in these patients. Hyllén and colleagues¹⁸⁵ focused on the role of pulmonary hypertension as part of the disease complex also showing poor right ventricular function.

This confirms the need for further study and reinforces our thinking that tricuspid regurgitation of any origin is detrimental to the right ventricle. It is of interest to notice that this also applies to any nonvalvular procedure as well. Transventricular pacing is becoming also a matter of discussion in current times when all types of intracardiac devices for the treatment of malignant arrhythmias and heart failure are implanted in escalating proportions under an increasing number of more or less powerful indications.¹⁸⁶ The effect of regurgitation after single or multiple lead implantation across the tricuspid valve is definitely not known, and more information is needed to update current knowledge.^{187,188}

Organic disease is still a significant problem in non-Westernized countries, and it continues to contribute to the burden of valve disease¹⁸⁹ and cannot be neglected. Once again, the lack of large series may preclude drawing conclusions, but current knowledge indicates that the problem continues to be the worse profile of patients with long-standing tricuspid regurgitation in patients with rheumatic heart disease. Rodríguez-Capitán and colleagues¹⁹⁰ have recently pointed out the problem in another important series of patients with rheumatic involvement. Rheumatic disease involves all valve structures, which is the reason repair rates are much lower than in functional disease. In Westernized countries the incidence of organic disease may be estimated around 15% for patients¹⁹¹ requiring surgery although some series may show higher incidence.¹⁹⁰ As the results of tricuspid surgery are usually less predictable than its mitral counterpart, there are still gaps between the problem, the proposals, the solutions, and the outcomes. In its elegant contribution, Gonzalez-Santos and Arnaiz-Garcia¹⁹¹ have briefly and thoughtfully addressed the problem.

The indications for surgery of tricuspid regurgitation are becoming clear when it comes to the recommendations. The accumulation of information has led to modifications of Practice Guidelines in the past 5 years; however, in the case of tricuspid surgery, we are still missing well-designed controlled studies. Most of the information comes from observational studies, short series, and expert opinion. Current guidelines show some differences, and the most recent confirm that for both primary and functional tricuspid regurgitation in patients requiring left-sided valve surgery, tricuspid surgery is a must as expressed with class I recommendation.^{192,193} The remaining indications still remain in the IIa level.

Finally, from the methodology standpoint, the lack of prospective controlled studies still makes the decision-making process somewhat uncomfortable. It is not that we may not have the ideal tools for analysis, it is the fact that the tricuspid valve has consistently been neglected by many in the community since the days of Braunwald's contribution⁹⁰; this is easily represented by literature data. As we have already pointed out, a quick search through the United States National Library of Medicine using the terms *aortic valve*, *mitral valve*, and *tricuspid valve* yielded the following number of articles with these terms in the title: 13,608 (44.8%), 14,134 (46.6%), and 2625 (8.6%), respectively. When the search was limited to the twenty-first century, the observed results were

7736 (55.0%), 5238 (37.3%), and 1079 (7.7%). By conducting such a brief, quick, and eventually inaccurate search, we understand that less attention has been paid to a valve that has more than functional impact on late outcomes¹⁹⁴; this highlights the difficulties in achieving evidence as to what the best therapeutic options could be. The series of Rodríguez-Capitán and colleagues¹⁹⁰ is an accurate description of a specific environment; the indications are restrictive and limited to patients with advanced or organic valve disease as discussed by Gonzalez-Santos and Arnaiz-Garcia.¹⁹¹ The ultimate fact is that because of the high proportion of patients with organic valve disease or previous surgery, or both, surgery carries a high risk. Outcomes are frequently suboptimal with high mortality rate and poor functional status.

Evidence

There is little scientific evidence available regarding surgery of the tricuspid valve. Currently, the drivers for evidence are controlled studies, systematic reviews, and meta-analyses. Although international databases are filled with all types of articles related to all forms of treatment of the tricuspid valve, the actual number of published methodologically sound articles is scanty. The recent contribution by Parolari and colleagues¹²⁷ has confirmed that when analyzing the short-term outcomes of ring versus suture annuloplasty, there are only two prospective randomized studies separated by almost 30 years.¹⁹⁵⁻¹⁹⁶ The remaining knowledge is reduced to a number of important retrospective studies. When analyzing long-term outcomes, the same authors found no prospective randomized study. Interestingly enough and despite the lack of controlled studies, the median survival at 14 years after ring and non-ring repair was not statistically different among groups. A different topic is residual tricuspid regurgitation. In this case, patients who underwent ring repair performed better than patients with non-ring repair with statistically significant differences favoring prosthetic ring implantation in functional tricuspid regurgitation. In other words and as expressed by Parolari and colleagues,¹²⁷ the patients with non-ring repair had twofold higher risk of recurrent tricuspid regurgitation; this affected late reoperations.

These studies addressed ring versus non-ring repair in functional tricuspid regurgitation. We know that in the so-called Westernized countries, it is rare to find organic disease, which is more typical of rheumatic valvular involvement. The aftermath of literature search is that we still have limited evidence to produce robust conclusions as to which is the better therapy in specific subgroups of patients. It seems then that the meta-analysis of Parolari and colleagues¹²⁷ and the best-evidence topic constructed around the use of ring or non-ring repair in tricuspid regurgitation by Khorsandi and colleagues¹⁹⁷ support the use of ring repair for moderate or severe tricuspid regurgitation. However, there are still a number of unsolved questions as thoughtfully addressed by De Vega in a recent editorial¹⁹⁸ on the long-term results of Guenther and colleagues¹⁹⁹ who presented one of the largest retrospective series of tricuspid repair with 717 patients undergoing both ring and non-ring repair,

concluding also that ring repair is associated with improved survival and lower reoperation rate. The type of disease, the type of patient, the need for reoperation, and its timing may justify a more selective approach to the patient, as proposed by Yilmaz and colleagues from the Mayo Clinic.²⁰⁰

THE FUTURE

In the past 20 years, we have witnessed the booming of minimal access surgery, which is an established approach to the surgical therapy of cardiac disease. Current trends in sick patients are moving toward decreasing the size of the access and the invasiveness of the procedures, aiming at decreasing the effects on physiology.²⁰¹⁻²⁰³ In tricuspid valve surgery, the main drivers for failure are the long-standing disease, the preoperative condition of the patient, and the number of prior operations. They are clearly interrelated.

Cardiac surgery has changed as imaging has greatly improved preoperative diagnosis. The advent of two-dimensional echocardiography and Doppler velocity analysis represented a step forward helping physicians in better understanding heart valve disease.⁶⁸ Atrioventricular valve physiology is better known because of Doppler echocardiography,²⁰⁴ and accurate estimates of valve regurgitation are the consequence of the input given by Doppler analysis and color-mapping. Doppler echocardiography has been shown to have higher sensitivity than contrast echocardiography.²⁰⁵ Color-flow was shown early to be quick and simple in the interpretation of continuous wave Doppler and was an appropriate companion to Doppler, although there were historically some doubts about the investment needed to purchase the equipment.²⁰⁶

Doppler echocardiography and color-flow mapping has become the most useful tool in diagnosis and quality assessment in surgery. We do not understand an operating room without echocardiography. Postoperative evaluation of any cardiac surgical patient heavily relies on echocardiography. The preoperative assessment of valve lesions and ventricular function before the initiation of an operation and the intraoperative evaluation after completion of cardiopulmonary bypass or after off-pump operations are of utmost importance in adult and pediatric cardiac surgery as, of course, information on morphology and function is required for all types of procedures.²⁰⁷⁻²⁰⁸ As we move toward increasing use of technology, monitoring is a key requirement for improving quality.²⁰⁹ Therefore, imaging and technology are going to play an important part in the future of cardiac surgery.

Imaging

Two- and three-dimensional echocardiography and cardiac magnetic resonance are currently the most important imaging techniques for assessment of valve heart disease. The rapid evolution of echocardiography as a diagnostic tool has led to the implementation of newer techniques like strain imaging. Therefore, we are

learning newer definitions, formulas, and calculations from speckle tracking echocardiography.²¹⁰⁻²¹³ As it happened almost three decades ago, the incorporation of these techniques into clinical practice are to revolutionize our knowledge and approach to tricuspid valve disease.

The morphology of the right ventricle is shaped in a crescent and truncated manner, and it has separated inflow and outflow sections. This complex anatomy plays a role in the prognosis of heart disease, the development of functional tricuspid regurgitation, and the interpretation of pulmonary hypertension. It is generally agreed that the variability in the tricuspid annulus diameter plays a role in the indication for tricuspid annular remodeling through annuloplasty. The measurements of the annular diameter at mid-systole and early diastole and right ventricular volumes are part of the surgical strategy.²¹²

It is then time to gain knowledge in the new quantitative methods in two-dimensional and three-dimensional echocardiography. Ongoing research confirms that there are a number of variables that influence diameters in normal volunteers; therefore, this has to be taken seriously in the consideration of diseased individuals for appropriate surgical planning.²¹² The use of different planes of right ventricular analyses is also useful in estimating the clinical effects of pulmonary hypertension. Transverse and longitudinal right ventricular function are reliable markers for cardiac function and high pulmonary artery pressure, respectively.²¹³ Imaging has therefore evolved into a complex field that is continuously developing and influencing surgical practice. The assessment of tricuspid regurgitation is of utmost importance for the surgeon because of the complexity of a nonplanar structure such as the tricuspid valve annulus. Surgical treatment of tricuspid valve disease is still a challenge as per the decision and execution; however, surgeons have higher-quality preoperative information to navigate more accurately through a complex decision-making process.

Newer Technologies, Newer Devices, Newer Philosophies

The accumulated knowledge on tricuspid valve surgery indicates that tricuspid regurgitation secondary to left heart disease is the most common cause of insufficiency of the right atrioventricular valve. The controversy is still alive as to the superiority of ring versus non-ring repair, and it has been addressed in this chapter. According to recent information, it seems that ring repair¹⁹⁹ might have better long-term outcomes regarding survival and freedom from reoperation; the remaining question is whether improving the design of rings might lead to even better outcomes. It is likely that technology comes into aid in the future.

Rings

Three-Dimensional Rings

The tricuspid valve is a nonplanar structure. Rigid rings were initially not design for such geometry, and a number of prior reports are based on rigid rings like the Carpentier-Edwards ring. The aim of newer rings is to

restore the nonplanar geometry of the tricuspid valve annulus. There is scant experience published so far, but the work of Ratschiller and colleagues¹³⁹ with a novel three-dimensional device (Contour 3D, Medtronic, Inc.) sounds attractive. In their experience, the results have been encouraging up to 2 years of follow-up, with a low rate of residual tricuspid regurgitation at hospital discharge, a low reoperation rate, and an excellent early functional outcome. It is evident that the follow-up is still short and extended follow-up is warranted to ascertain eventual superiority over previously tested devices.

The field of three-dimensional rings has still to sustain the test of time. The available experience is limited in time and figures. A previously tested device, such as the MC3 three-dimensional annuloplasty ring (Edwards Lifesciences), has yet to be supported with long-term outcomes, which is mandatory for any device designed to improve valve competency. Although the concept and some devices have been commercially available for some time, no large series have confirmed results over time.²¹⁴⁻²¹⁶ De Bonis and colleagues²¹⁴ analyzed a series of 140 patients and concluded that the three-dimensional ring provides satisfactory early results that remain stable at midterm follow-up. Actuarial survival at 3 years was 94.8%, and the mean follow-up 23 months. Freedom from tricuspid regurgitation >2 was 88%. Annular dilation leading to residual valve insufficiency after ring annuloplasty alone was not the only mechanism involved.²¹⁴ It is also evident that the future has to bring us robust data based on extended observation on these devices.

Biodegradable Annuloplasty

The concept of “vanishing annuloplasty” is definitely not new. Two decades ago, Duran and colleagues²¹⁷ launched what was a new concept at the time after collecting information from animal experiments in sheep in which the authors performed tricuspid suture annuloplasty. The animals were euthanized, and postmortem examinations showed that the suture material had been replaced with fibrous tissue.²¹⁷ These experiments were followed by a clinical series including 25 patients who had no regurgitation 2 years after DeVega annuloplasty with resorbable material.²¹⁸ What happened in these past 20 years? The concept was not embraced by the community, and little information on clinical series is available. The initial concept of a DeVega annuloplasty using resorbable sutures was replaced with an annuloplasty ring using biodegradable materials, as tested in the animal setting by Kalangos and colleagues.²¹⁹ The animal experiments yielded a complete degradation of the biodegradable suture being replaced with fibrous tissue. No safety concerns were raised because of the implant being close to the left circumflex and the great cardiac vein.

However, there is newer interest in this concept of vanishing annuloplasty despite the lack of robust data over time. Little information is available from reports by Myers and colleagues²²⁰ collecting data on both atrioventricular valves. In addition, the main indication in the adult seems to be infection as analyzed by the same authors.²²¹ The Bioring Kalangos annuloplasty ring

(Bioring, Lonay, Switzerland) has been shown to stabilize the native annulus in a variety of conditions also in the clinical setting.^{222, 223} However, the series are small and the average follow-up is less than 10 years.

The revival of the biodegradable annuloplasty is related to newer developments in biomaterials. A number of biological scaffolds are being developed and intended to be replaced by autologous tissue.²²⁴ There is substantial research going on at the moment with biological scaffolds based on extracellular matrix (ECM) that can be obtained from a variety of tissues. The question is whether these scaffolds can be used for annular stabilization under the same rationale that the prior vanishing sutures were used for annuloplasty. The commercially available ECM patches address leaflet tissue reconstruction. As this is an evolving field, the possibility of annular remodeling using these materials cannot be excluded in the future. Speculation is based on the scant experience in different forms of valve therapy with ECM.

Valves and Techniques

Transcatheter valve implantation is the current revolution in the treatment of patients with heart valve disease. The confusing and imprecise term *structural valve disease* seems to be well related to this newer form of therapy of heart valves. It is difficult to understand the pathology, although the medical community is guilty of resorting to phraseology that relies on commercial interests. This has recently been addressed by De Maria in an elegant editorial.²²⁵ That said, the newer developments in valve technology and technique are related to the evolution of the treatment of this structural disease. In cardiac surgery, there is no room for confusing terminology. Current trends in this field are again toward reducing the surgical access and invasiveness by avoiding cardiopulmonary bypass. As we agreed on the usual poor clinical condition of patients with advanced tricuspid disease and the fact that a significant proportion has a number of prior operations, any form of therapy that may complement an appropriately designed medical therapy is welcome. The options for transcatheter valve implantation in the tricuspid position are currently under investigation. It is to be expected that this evolving field will bring advanced solutions for this subgroup of valve patients.

As in the aortic position, there were pioneering efforts such as using balloon dilation of the native tricuspid valve and prosthetic tricuspid implants more than 20 years ago²²⁶⁻²²⁷ that paved the way for future developments. Encouraged by the initial results of valve-in-valve implantation in the aortic position, several authors have jumped into the tricuspid position and tried the valve-in-valve concept. The positive experiences of transcatheter implantation of valves in the pulmonary position were instrumental in addressing the tricuspid position as well. Valve-in-valve seems to be an attractive concept that needs to undergo the test of time. The initial experience reported by Hon and colleagues²²⁸ opened the door to expand transcatheter approach in this group of usually high-risk patients. Roberts and colleagues²²⁹ reported the first short series of implants in congenital and acquired heart disease including 15 cases with a short follow-up of

4 months.²²⁹ They reported one case of early prosthetic valve endocarditis. There is, therefore, accumulated optimism among cardiologists and surgeons, as this is an approach that may help to reduce the risk of surgery in the setting of advanced tricuspid disease. This is definitely an emerging field in cardiology and cardiothoracic surgery. In the past couple of years, a number of reports addressing complex cases have become available. In some cases, isolated tricuspid implants have been attempted, and there are also combined multivalvular implants with good immediate outcomes.²³⁰⁻²³⁴ Current experiences are mostly related to treating patients in poor condition after prior tricuspid valve operations in which there are degenerated tissue valves or perivalvular leaks.²³⁵⁻²⁴⁰ This growing body of information suggests that the future of percutaneous treatment of tricuspid diseases is going to evolve rapidly. The common issue across recent literature is the risk of patients with single or multiple prior interventions and dysfunctional tissue valves. Congenital and acquired disease will be targeted. It is likely that adult patients with previously treated congenital defects will increase the pool of patients that will develop right heart failure or dysfunction of valves or conduits that were implanted to treat the right ventricular outflow tract.

The Melody stented bovine jugular vein conduit (Medtronic, Inc.) and the Edwards Sapien stented pericardial valve (Edwards Lifesciences, Irvine, CA) have been used in the right atrioventricular position. In all these reports, the behavior of the valve seems to be appropriate although the follow-up is still short, with no reports reaching the mark of 5 years. A multicenter French study has been able to collect 71 cases of transcatheter tricuspid valve implantation for failing tissue valves.²⁴¹ Stenotic and regurgitant lesions were treated. The authors stated that there was procedural success in all, although there were two cases of embolization into the right atrium. This raises, of course, some concerns as to the accuracy in definitions and reporting. Another series from the Mayo Clinic has also reported good periprocedural results in 19 patients.²⁴² The periprocedural problems were related to vascular access. This study also lacks short-term follow-up. Most of the short-term information available is related to the hemodynamic behavior of the implant.²⁴³

As there is limited, if any, information on the follow-up after these procedures, it is also to be expected that some problems develop over time. Whisenant and colleagues²⁴⁴ recently reported thrombosis after valve-in-valve implantation. Early valve failure as described by Bentham and colleagues²⁴⁵ and endocarditis raises some concerns about safety and viability that need to be confirmed in the future as follow-up information is accumulated. Prosthetic valve endocarditis after transcatheter valve implantation is emerging as a new entity of difficult diagnosis and treatment that also entails a high risk.²⁴⁶⁻²⁴⁸ As most of the information on transcatheter valve endocarditis is related to the aortic position, some isolated cases in the right atrioventricular position have also been reported in some of the above-mentioned studies.

What seems clear is that the prospects for the development of the transcatheter valve implantation in the right atrioventricular position are good considering the rapidly

increasing number of reports. As in every case of innovation, it is mandatory to collect robust data on the follow-up.

The Controversy: Prophylaxis?

Do we need to be proactive when dealing with trivial or mild tricuspid regurgitation? Do we need to address marginally dilated annuli? There are a number of questions out there with no clear answer. This is a controversy in the subset of patients with functional tricuspid regurgitation. In the case of heart transplantation, it seems appropriate to perform tricuspid annuloplasty in the donor heart because there is information that confirms reduction of mortality and the degree of valve regurgitation. Suture-based annuloplasty has been advocated by Jeevanandam and others.^{249,250} However, this is not very clear in dilated tricuspid annulus undergoing surgery for degenerative mitral regurgitation. The current guidelines give a class IIb recommendation for annuloplasty when there is mild annular dilation without pulmonary hypertension.²⁵¹ Data from Benedetto and colleagues²⁵² suggest that prophylactic tricuspid valve annuloplasty in patients with dilated tricuspid annulus undergoing mitral valve surgery was associated with a reduced rate of tricuspid regurgitation progression, improved right ventricular remodeling, and better functional outcomes. Furthermore, the decision could be facilitated by intraoperative measurements of the indexed tricuspid annular circumference as suggested by Zhu and colleagues²⁵³ over a value of 83 mm/m². Data from Teman and colleagues²⁵⁴ regarding 21 patients who underwent reoperation for functional tricuspid regurgitation also suggest that a more aggressive approach to annuloplasty in primary mitral operations is to be strongly recommended. A recent systematic literature review and meta-analysis concludes on the need to develop specific scores for identification of patients at risk of developing functional tricuspid regurgitation.²⁵⁵

The Research

There is ongoing research related to the tricuspid valve. Part of this research is aimed at developing models to test the newly developed devices, as there is no information that could be extrapolated into the human setting per the follow-up of transcatheter implants. There is nothing new on this, as the early steps toward percutaneous implantation of valves in the atrioventricular positions were taken two decades ago by Boudjemline and colleagues.²⁵⁶ The technological advance in percutaneous valves owing to the massive investment by the manufacturers has prompted an increase in the number of contributions and the evaluation of the concept in different models. Bai and colleagues²⁵⁷ have developed a simple percutaneous model of tricuspid regurgitation in sheep that may help in the assessment of implants. These authors had previously pioneered tricuspid research by implanting homemade pericardial porcine stented valves in sheep, providing tricuspid competence.²⁵⁸ An acute model of tricuspid insufficiency has been created by Lauten and colleagues²⁵⁹ in sheep with the goal of

investigating the effectiveness of valved stents implanted in the vena cavae with good short-term outcomes. There was significant reduction of venous regurgitation and improvement in cardiac output after the implantation of caval stents. The underlying message is that all efforts are directed toward decreasing the risk of surgery in patients with advanced tricuspid disease.

There is also ongoing research related to tricuspid endocarditis. Tricuspid valve endocarditis is cured with antibiotic therapy in more than 95% of the cases, regardless of the pathogen and mode of acquisition.²⁶⁰ Tricuspid valvectomy was a life-saving maneuver in sick patients with addictive behaviors and was documented by Arbulu and colleagues.¹³¹ However, residual massive tricuspid insufficiency led to severe right heart failure that later required valve replacement. As discussed earlier, there were a number of attempts at evaluating mechanical and tissue valves for replacement in this setting, with disappointing results because of valve dysfunction secondary to persistent addiction, although better results were achieved with mitral valve transplantation into the tricuspid position.²¹ The development of biological scaffolds has opened a new field of research. Recently, Gerdisch and colleagues²⁶¹ reported the experience of a number of surgeons with extracellular matrix cylinders in tricuspid valve endocarditis with promising results.²⁶¹ The intriguing and attractive field of scaffolding will definitely be a part of the future in valve research. The aim is to combine an easy implantation and biocompatibility. This feasibility study has proved that ECM can be used for valve replacement. However, recent additional information suggests that a word of caution is mandatory because of unexpected early failure in a given implant.²⁶² Follow-up information and more discussions are warranted.

A highly innovative approach was introduced recently by Bajona and colleagues.²⁶³ Because functional tricuspid regurgitation is characterized by annular dilation and leaflet tethering in a dilated right ventricle, these authors addressed the right ventricle treating tricuspid insufficiency by inserting a catheter-guided, inflatable balloon across the tricuspid valve to eliminate central regurgitation without hemodynamic compromise. The attractive hypothesis is that a screw-in lead with a percutaneous reservoir for balloon volume adjustment will provide added utility. These ex vivo experiments with calf valves have shown promising results regarding hemodynamics. This is also a field to explore, and more developments are expected.

PROSTHETIC VALVE ENDOCARDITIS

SUMMARY

Endocarditis of a patient's native heart valve is defined as *native valve endocarditis* (NVE), and endocarditis of a prosthetic device is termed *prosthetic valve endocarditis* (PVE). The incidence of NVE in developed countries is approximately 1.7 to 7.0 cases out of 100,000 persons per year and is highest in older adults.¹⁻³ NVE typically affects the left heart, with right heart involvement observed in only 5% to 10%.^{3,4} Whereas the overall incidence of NVE and PVE has remained consistent over the past several decades, the causes and risk factors for both NVE and PVE have changed in recent years from rheumatic heart disease to degenerative valve disease, intravenous drug use, intravascular devices, and nosocomial infections predominating.

NATIVE VALVE ENDOCARDITIS

Pathology

Two conditions must be present for the development of almost all cases of NVE: endocardial injury causing a disruption of the valvular endocardial surface, and subsequent infiltration of the injured site by bloodborne microorganisms, typically bacteria.⁵ Endocardial trauma results from degenerative calcific changes, rheumatic disease, mitral valve prolapse, regurgitant jet flow, congenital abnormalities (e.g., bicuspid aortic valve), or iatrogenic causes (e.g., cardiac catheterization). Endocardial injury results in the deposition of platelet-fibrin products, which then serve as a nidus for the attachment of microorganisms. Organisms that cause NVE enter the bloodstream through compromise of the skin, mucosal surfaces, or other sites of focal infection. Common causes for bacteremia or fungemia that predispose to NVE include

intravenous drug use, indwelling catheters, debilitated condition, medical procedures, and even simple events such as tooth brushing and mastication.⁵⁻⁷

In all cases of NVE, complications and symptoms of the infection may be divided into two categories. Systemic manifestations of the disease result from sepsis and embolic phenomena, such as stroke, kidney failure, or fever. In addition, there are sequelae that are the direct results of infection and the location of the infection with respect to any critical myocardial anatomy.

In native *aortic* valve endocarditis, infection may spread into the aortic annulus, destroy the aortic valve, or result in paravalvular abscess formation. Conduction system pathology may result, including heart block, depending on the extent of the infection. Other complications include cardiac fistulas, coronary and systemic embolization of vegetations, stroke, cerebral infarction, and mycotic aneurysms. Large aortic valve vegetations can prolapse into the left ventricular cavity, contact the anterior leaflet of the mitral valve, and cause subsequent double-valve endocarditis. Typically, aortic insufficiency results from aortic valve endocarditis. Untreated cases can lead to destruction of the fibrous trigones and the tissue between the anterior mitral leaflet and the aorta. Heart failure may occur because of volume overload secondary to aortic insufficiency. Fistulas between the aorta and right atrium are also possible.

The most common site of vegetations in native *mitral* valve endocarditis is the mitral valve leaflet near the annulus on the atrial side. Vegetations may be located anywhere on the leaflets or the chordae, and they may occur on the ventricular side as well. Vegetations and debris may destroy part of the ventricular tissue. Complications include invasion into the atrioventricular (AV) groove proper and abscess formation, with severe cases

leading to separation at the AV junction and complete destruction of the fibrous skeleton surrounding the valve.

Native *tricuspid* valve endocarditis usually affects the free margins of the leaflets with relatively infrequent involvement of the annular tissue. Complications of tricuspid NVE include cardiac and pulmonary sequelae as a consequence of valve destruction and embolism. Tricuspid regurgitation with chamber dilation and right heart failure can result, and local extension can cause abscess and fistula formation. Septic pulmonary emboli lead to pulmonary infarction, pulmonary abscess, empyema, and, in rare cases, mycotic aneurysms of the pulmonary arteries.

Microbiology

Endocarditis is caused principally by staphylococci and streptococci. The most common agents are *Staphylococcus aureus* (32%), viridans group streptococci (18%), enterococci (11%), coagulase-negative staphylococci (11%), and *Streptococcus bovis* (7%).^{8,9} Gram-negative bacteria can also cause NVE and are classified into either the HACEK group (fastidious gram-negative bacilli, including *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) or non-HACEK group, with each accounting for approximately 2% of all cases. These organisms require a prolonged incubation period before growth and are often resistant to many antibiotics. Fungal NVE, usually caused by *Candida albicans* or *Aspergillus fumigatus*, is rare but can lead to devastating complications.^{10,11}

The microbiology of NVE differs somewhat depending on specific individual risk factors and demographics. For example, viridans group streptococci is more prevalent in community-acquired endocarditis, whereas the more virulent *S. aureus* is more common in nosocomial cases.^{1-3,8} NVE of the right heart is predominantly a disease of intravenous drug users, and in this population native tricuspid valve endocarditis caused by *S. aureus* is the predominant form of the disease.⁴

Approximately 2% to 7% of NVE cases are deemed “culture-negative endocarditis” when no microorganisms can be cultured from the blood or tissue samples.¹²⁻¹⁵ This occurs more frequently in developing countries, where fastidious or rare organisms are more likely to cause human infection. The most common reasons for culture-negative endocarditis in developed countries are administration of antimicrobial agents before cultures are taken, inadequate microbiological techniques, and infection with highly fastidious bacteria or nonbacterial pathogens (e.g., fungi). In all cases of culture-negative NVE, it is important to ascertain the absence of any underlying undiscovered infection and to initiate aggressive empiric treatment despite the negative culture data.

Diagnosis

Clinical Presentation

The onset of NVE usually begins with fever and malaise. Common physical examination findings include a new

heart murmur or change to an existing heart murmur, petechiae, splenomegaly, clubbing of the digits, splinter hemorrhages, Osler nodes, Janeway lesions, and Roth spots. The latter two are found almost exclusively in acute endocarditis when overwhelming signs of sepsis are displayed early in the clinical course. The virulence of the offending organism affects the severity of symptoms seen, with less virulent organisms such as viridans group streptococcus causing a subacute, protracted clinical course that often can be cured with antibiotics alone.

Laboratory findings include moderate leukocytosis, anemia without reticulocytosis, and hematuria. Blood cultures must be drawn from separate sites and usually help clinicians identify the infective organisms in cases of bacterial NVE. Cultures should be drawn before antibiotics are started.

Imaging Studies

Doppler echocardiography is the single most useful diagnostic modality for documenting endocarditis.¹⁶⁻¹⁹ Transesophageal echocardiography is the preferred study, with a sensitivity and specificity of 95% and 90%, respectively.²⁰ Transthoracic echocardiography is less sensitive for endocarditis but can be used when transesophageal studies are not feasible. Echocardiography can be used to identify vegetations, paravalvular leaks, abscesses, and fistulas. Patients with NVE and concern for metastatic or embolic disease should undergo further imaging with computed tomography (CT) scans of the abdomen and/or head as appropriate. Embolic involvement of the brain can also be investigated with magnetic resonance imaging (MRI).²¹

Duke Criteria

The diagnosis of endocarditis is based on a combination of clinical findings rather than a single test result. Several classification systems for the diagnosis of endocarditis have been published, but the most commonly used is the Duke system.²² First described by Duke University researchers in 1994, this system uses both clinical and pathologic criteria to confirm or reject the diagnosis of infective endocarditis. There are two groups of criteria: “major” (positive blood cultures, positive echocardiographic findings) and “minor” (fever, predisposing conditions, vascular phenomena, immunologic phenomena, equivocal microbiological findings). Based on the number of criteria met, cases are classified into three diagnostic categories: low clinical likelihood of endocarditis, possible endocarditis, and definite endocarditis. Definite endocarditis is diagnosed by documentation of two major criteria, of one major and three minor criteria, or of five minor criteria. Cases are considered possible endocarditis when either one major and one minor criterion or three minor criteria are identified. Most authorities accept a recently modified version of the Duke criteria, as shown in Table 82-1.²³

Management

Aggressive antibiotic therapy is the first and most important intervention in all cases of NVE. Antibiotics should

TABLE 82-1 Modified Duke Criteria for Infective Endocarditis**Major Criteria****Positive Blood Cultures for Infective Endocarditis**

Typical microorganism for infective endocarditis from two separate blood cultures:

Streptococcus viridans, *S. bovis*, HACEK group, *Staphylococcus aureus*, or community-acquired enterococci in the absence of a primary focus, or

Microorganisms consistent with infective endocarditis from a persistently positive blood culture, defined as:

At least two positive blood cultures drawn more than 12 hours apart, or

All of three or most of four or more separate blood cultures, with the first and last drawn at least 1 hour apart

Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer to *C. burnetii* greater than 1:800

Evidence of Endocardial Involvement

Echocardiogram positive for infective endocarditis: TEE recommended in patients with prosthetic valves, rated at least as "possible endocarditis" by clinical criteria, or complicated endocarditis, such as endocarditis with paravalvular abscess; TTE as the first test in other patients as follows:

Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation

Abscess

New partial dehiscence of prosthetic valve

New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

Predisposition: predisposing heart condition or intravenous drug use

Fever: temperature 38° C (100.4° F) or higher

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

Microbiological evidence: positive blood culture but does not meet a major criterion as noted above, or serologic evidence of active infection with an organism consistent with infective endocarditis

HACEK, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

From Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 30:633–638, 2000.

be started as soon as possible after obtaining blood cultures. Combination broad-spectrum agents should be administered empirically and then adjusted when culture data are available. Surveillance blood cultures and frequent echocardiograms, at least in the first two weeks after initiating treatment, can help to determine and follow the efficacy of therapy. Surgical intervention is indicated in patients who develop worsening symptoms and continued sepsis despite antibiotics. Early surgical

treatment is often required in cases involving virulent organisms such as *S. aureus* and gram-negative bacteria, as these infections will progress rapidly despite antimicrobial therapy. Fungal infection is an absolute indication for surgery.

For the cardiac surgeon, the first management decision is determining the optimal timing for operation. Should operation be undertaken now or after appropriate antibiotic treatment? Most indications for surgical intervention are not absolute, and therefore the decision to operate must be based on each patient's clinical status and assessment of the risks and benefits. In general, the more serious and persistent the symptoms and complications of any particular endocarditis case are, the more likely surgery should be undertaken sooner. Once the decision to operate has been made, expeditious intervention should occur. If an indication for surgery is identified, surgery should not be delayed to complete antibiotic therapy, as this has been associated with increased mortality.^{24–26}

With either mitral or aortic endocarditis, one common indication for immediate surgery is congestive heart failure. Early surgery in such cases is always warranted, as medical therapy alone is usually ineffective and associated with a poor prognosis. Risk factors for early mortality from NVE include New York Heart Association (NYHA) functional class IV heart failure, cardiogenic shock, advanced age, preoperative acute renal failure, paravalvular extension, and staphylococcal infection.^{24–26} In 2006, the American College of Cardiology and the American Heart Association (ACC/AHA) issued guidelines on the management of valvular heart disease, including recommendations on surgical treatment of NVE (Table 82-2).²⁷ In addition to heart failure, the generally accepted indications for surgery are ongoing sepsis, fungal infection, *S. aureus* infection, myocardial abscess, and recurrent systemic embolism. For aortic valve endocarditis, conduction abnormalities are a relative indication for surgery as well.

One subgroup of patients in whom delayed surgery is beneficial, however, is those with evidence of neurologic complications. A thorough neurologic evaluation should be performed in all endocarditis patients, including head CT and/or MRI studies if necessary, to assess for the type and degree of stroke or embolism. Ischemic embolic stroke is more common than hemorrhagic injury, but both are associated with a significant increase in morbidity and mortality.^{28–31} With cardiopulmonary bypass is the risk that an ischemic infarct may be transformed into a hemorrhagic one as a consequence of anticoagulation.²⁹ Thus, if feasible, any surgery should be delayed for 2 weeks after an ischemic stroke and for 4 weeks after a hemorrhagic stroke to reduce the risks of worsening neurologic symptoms and further intracranial hemorrhage.^{21,31–32} This is often a difficult judgment that must weigh the risk of further sepsis and embolization against the hemorrhagic risk of cardiopulmonary bypass anticoagulation. The possibility of mycotic aneurysms should be evaluated with cerebral angiography if clinically suspected and treated before valve surgery with antibiotics; such aneurysms are a contraindication for anticoagulation as well.

TABLE 82-2 2006 ACC/AHA Guidelines for the Management of Valvular Heart Disease

Class I—There is evidence and/or general agreement that surgery is indicated in patients with native valve endocarditis (NVE) with one of the following:

- Valve stenosis or regurgitation leading to heart failure
- Aortic or mitral regurgitation with hemodynamic evidence of elevated left ventricular end-diastolic or atrial pressures such as premature closure of the mitral valve with aortic regurgitation, rapid decelerating mitral regurgitation signal by continuous wave Doppler (v-wave cutoff sign), or moderate to severe pulmonary hypertension
- Infection caused by fungal or other highly resistant organism
- Complications such as heart block, annular or aortic abscess, or destructive penetrating lesions such as fistulas from the sinus of Valsalva to the right or left atrium or right ventricle, mitral leaflet perforation with infective endocarditis of the aortic valve, or infection in annulus fibrosis

Class IIa—The weight of evidence or opinion is in favor of the usefulness of surgery in patients with NVE who develop the following:

- Recurrent emboli and persistent vegetations despite appropriate antibiotic therapy

Class IIb—The weight of evidence or opinion is less well established for the usefulness of surgery in patients with NVE who develop the following:

- Mobile vegetations larger than 10 mm with or without emboli

From Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease). *J Am Coll Cardiol* 48:e1–148, 2006.

Surgical Considerations

The basic tenets of surgery for infective endocarditis are the same as that for débridement surgery of any abscess or infection. The overall principle and goals are meticulous, aggressive débridement with removal of all infected and necrotic tissue, appropriate reconstruction, and the prevention of further contamination. For most cases of NVE, débridement of the infected valvular tissue followed by “simple” valve repair or replacement remains the mainstay of surgical therapy and can yield satisfactory long-term results for patients who otherwise have a dismal prognosis.

Native Aortic Valve Endocarditis

The most commonly used incision in operations for infective endocarditis is the median sternotomy. This permits adequate exposure for planned operation as well as the possibility for extensive reconstruction if necessary. A low transverse or oblique aortotomy is typically used to access the aortic valve. In cases where the extent of infection is limited to the cusps of the valve leaflets, excision of the valve and replacement with a biological or mechanical prosthesis is usually sufficient to eradicate the

infection. There is some debate about the optimal choice of prosthesis in patients with active endocarditis, but the available evidence suggests that bioprosthetic and mechanical valves are comparable in overall effectiveness and rates of recurrent infection for routine endocarditis.³³ If the infection is extensive and a large abscess cavity exists, then the prosthesis of choice is an aortic homograft with root replacement, as this has been shown unequivocally to have a better cure rate.^{38–41}

Involvement of the aortic annulus requires radical resection of all grossly infected areas, leaving a rim of healthy tissue. Any defects must then be reconstructed before implantation of a prosthetic valve. The type of reconstruction depends on the extent of resection performed. Autologous or bovine pericardial patches may be used for smaller and moderate sized defects, whereas Dacron fabric may be suitable for reconstruction of larger areas or the aortic root.^{34–37} If more than 50% of the annulus has been destroyed or there is extensive ventricular-aortic discontinuity, an aortic homograft remains the treatment of choice.^{38–41}

Aortic root abscess presents a particularly challenging problem, as it can be extensive and involve surrounding structures such as the fibrous trigones, interventricular septum, left and right atria, and pulmonary artery.^{34–35,42–44} Again, the most important goal in these cases is meticulous débridement and resection of all infected and necrotic areas, with secondary concern given to reconstruction of defects. These patients will often require replacement of the entire aortic root with reimplantation of the left and right coronary arteries as well as repair of any involved structures. An aortic valve homograft is preferable when there is involvement of the intervalvular fibrosa, not only because of the extent of infection but also because anterior leaflets of the homograft’s mitral valve can be used as a patch for the affected fibrous trigones (Fig. 82-1).^{41–42,44}

Native Mitral Valve Endocarditis

As in surgery for the aortic valve, the median sternotomy is the preferred approach for mitral valve operations. The mitral valve can be accessed via a left atriotomy through the Sondergaard groove or transseptally. Following radical débridement and resection of all infected tissue, the two general reconstructive options available are valve repair and valve replacement. Mitral valve repair is an attractive option as long as adequate resection of all infected tissue does not compromise the durability of valve reconstruction. In cases with extensive destruction, prosthetic valve replacement is performed. In clinical practice, however, virtually all cases of mitral valve endocarditis are treated with valve replacement. Pericardial pledgets are typically used instead of cloth pledgets when suturing the prosthesis to minimize the amount of foreign material implanted in the setting of an active infection.

Mitral valve endocarditis may be caused by vegetations from aortic valve endocarditis prolapsing into the left ventricular cavity and contacting the anterior leaflet of the mitral valve, resulting in “drop lesions” and subsequent double valve endocarditis. If involvement of the mitral valve is limited to a small portion of the anterior

FIGURE 82-1 ■ Aortic root replacement and homograft reconstruction. **A**, The infected tissue is débrided and excised, and the coronary ostia are preserved. **B**, The defect is reconstructed using the mitral valve leaflet of the homograft. (From Sabik JF, Lytle BW, Blackstone EH, et al: Aortic root replacement with cryopreserved allograft for prosthetic valve endocarditis. *Ann Thorac Surg* 74:650–659, 2002.)

leaflet, the affected area can be resected and the defect repaired with an autologous or glutaraldehyde-preserved pericardial patch.⁴⁵⁻⁴⁷ Cases of double valve endocarditis, however, frequently require extensive resection and reconstruction of both aortic and mitral valves. Although pericardial patch repair can be performed to reconstruct the fibrous trigones before valve replacement, in many cases an aortic valve homograft may be a preferable alternative. With the latter, aortic valve and root replacement are performed with the homograft in an anatomic position, and the aortomitral curtain of the homograft is used to reconstruct the base of the native anterior leaflet. If repair is not possible, the mitral valve prosthesis is sutured to the intervalvular fibrosa of the homograft.^{21,38-41,53}

The most frequent site of involvement on the posterior leaflet is the P2 segment. Lesions in this area without concomitant extensive annular destruction are amenable to treatment by quadrangular resection with sliding repair and remodeling annuloplasty. Complex and larger infections that extend into the annulus may necessitate resection of substantial amounts of annular tissue, resulting in sizable defects that require reconstruction of the mitral annulus in addition to valve replacement.

Two different approaches for reconstruction of the mitral annulus have been described by David and Carpentier. The David technique involves the use of autologous or bovine pericardium to reconstruct the annulus (Fig. 82-2).^{43,50-51} A semicircular patch is used to cover the defect, with one side secured to the left ventricular endocardium and the other side sewn to the atrium. The new prosthetic valve is then anchored to the patch. A circular patch can be used in cases where the entire circumference of the annulus must be reconstructed.

The Carpentier technique for mitral annular reconstruction consists of placing figure-of-eight sutures at the atrial and ventricular edges of the defect to close the AV

groove.⁵² With this approach, traction exerted by the sutures reduces the size of the annulus and restores the AV groove without injuring the circumflex vessels. The prosthesis is then secured to the reconstructed annulus. However, if an extensive defect exists in the AV groove because of extensive infection, the David technique is preferable.

Native Tricuspid Valve Endocarditis

Although isolated tricuspid valve surgery can be performed through a right thoracotomy or mid-sternotomy, the median sternotomy is again the most appropriate incision for endocarditis because of the possibility of more extensive surgery. Access to the tricuspid valve is achieved via a right atriotomy made parallel to the AV groove, with care taken to avoid injuring the sinoatrial node and the right coronary artery.

The three main surgical options for tricuspid NVE are total valve excision without valve replacement, valve reconstruction, and valve replacement. Valvectomy without simultaneous replacement avoids the use of any prosthetic material and can be performed in the beating heart, but this often results in massive tricuspid regurgitation and ventricularization of right atrial pressures. Young, otherwise healthy patients may tolerate this hemodynamic alteration, but 20% of patients undergoing this procedure develop right heart failure and require reoperation for implantation of a prosthetic valve.⁶³⁻⁶⁵

Valve replacement with either a biological or a mechanical valve is an option that may be particularly appropriate in cases involving two leaflets or the entire valve. Implantation of a prosthesis, however, obviously exposes the patient to valve-related complications such as thrombosis and recurrent endocarditis. The choice of mechanical versus bioprosthetic valve is debated, but

FIGURE 82-2 ■ Large defects in the mitral annulus and central fibrous tissue can be reconstructed using a pericardial patch. (From David TE, Feindel CM: Reconstruction of the mitral annulus. *Circulation* 76:III102–III107, 1987.)

several studies have demonstrated no significant difference in survival and complication rates between these types in the tricuspid position.^{66–68} The overall incidence of recurrent tricuspid valve endocarditis is quite low after valve replacement, but the risk is particularly high in injection drug users and older adults.^{69–71} These two patient populations are associated with the increased risk factors that predisposed them to the development of endocarditis in the first place—intravenous drug use and the presence of foreign bodies such as transvenous pacemaker leads. Valve replacement with a mitral homograft in the tricuspid position has been shown to have promising results, and this may be an option worth considering in patients in whom valve replacement is necessary but who are at high risk for reinfection.^{72–73}

Most cases of native tricuspid valve endocarditis can be successfully treated with valve reconstruction following radical débridement. A number of different approaches have been reported, including posterior leaflet excision (Kay plasty), repair with pericardial patches, commissuroplasty, sliding plasty, and use of artificial chordae.^{74–77} The particular technique applied depends on the amount of reconstruction needed. Repair can be accompanied by annuloplasty to help achieve leaflet coaptation without

excessive tension on the repaired valve, although some surgeons will avoid placing a ring to minimize foreign material. Annuloplasty may be especially helpful in patients with extensive resection and reconstruction. Patients usually tolerate the initial valvular insufficiency after tricuspid repair, and valve competence generally improves over time.⁷⁸

Results

The mortality rate for patients who undergo surgery for NVE has historically been high but has improved significantly over the past several decades. Long-term survival rate is satisfactory, with recent series reporting 15-year survival rates of 50% to 60%.^{54–55} Predictors of poor operative outcome include preoperative shock, paravalvular abscess, left ventricular ejection fraction less than 40%, and infection with *S. aureus*.⁵⁴ Increased age, comorbidities, annular abscess, and acute preoperative myocardial infarction are associated with the development of late complications.⁵⁵ The most frequent postoperative complications for both aortic and mitral NVE include reexploration for bleeding or tamponade, cerebrovascular accident, heart block, new renal failure, sternal infection, atrial and ventricular arrhythmias, valve dehiscence, recurrent endocarditis, and persistent sepsis.

The mortality rate for “simple” cases of native aortic valve endocarditis with involvement limited to the cusps of the aortic valve is reported to be less than 10%, whereas more complex cases carry a significantly higher rate.^{35–37,48–49}

Several studies have demonstrated outstanding results with mitral valve repair in NVE, with lower mortality and higher long-term survival rates when compared to mitral valve replacement.^{56–62} The rate of recurrent infection was also lower with valve repair. The reasons that most likely account for these observations are that foreign material is avoided in the setting of active infection with valve repair and that the sickest patients with the most advanced disease undergo valve replacement rather than repair.

Both tricuspid valve reconstruction and replacement in patients with NVE have been shown to have excellent mid- and long-term results, although the general consensus is to attempt repair if feasible.^{66–68,79,80} The prognosis for patients with NVE involving both the right and left heart is significantly worse when compared to those with isolated right-sided endocarditis, independent of the procedure performed.⁸⁰ This is most likely explained by the fact that patients with right- and left-sided NVE usually have more comorbidities and present with worse preoperative conditions than patients with isolated right heart involvement.

PROSTHETIC VALVE ENDOCARDITIS

Prosthetic heart valves may become infected early on in placement or at any point throughout the lifetime of the valve. In early PVE, it is presumed that the bacteria are introduced at the time of surgery, or via indwelling catheter lines in the immediate perioperative period, which

then migrate to the new device. Risk factors associated with early PVE include but are not limited to infective endocarditis of the native valve, history of intravenous drug abuse, male gender, and a long cardiopulmonary bypass time.⁸¹

Late PVE is classified as PVE occurring more than 12 months after valve placement. The offending organisms and pathogenesis of late PVE more closely resemble what has been described in NVE.⁸² The most common scenario of late PVE involves a transient bacteremia that occurs as a result of direct organism inoculation into the bloodstream, which then localizes onto the prosthetic valve. Dental procedures are a common culprit for bacterial inoculation.

The most common organism responsible for early PVE is *Staphylococcus epidermidis*. Late PVE microorganisms tend to be more similar to those encountered in NVE, such as viridans group streptococci and *S. aureus*.

The clinical signs and symptomatology associated with PVE are similar to those encountered with NVE. The important distinguishing factor between the two is that cardiac complications, such as new and changing murmurs as a result of a paravalvular leak secondary to valve ring dehiscence, and conduction defects from abscess extension into the intraventricular septum are more prevalent in PVE and require urgent if not emergent surgical intervention.

Diagnostic confusion may arise in the immediate postoperative period. Blood cultures that demonstrate staphylococci and yeast likely represent true PVE. Gram-negative bacteremia in an early postoperative patient is statistically more likely to be a result of an indwelling catheter infection, not PVE. In patients with late PVE caused by staphylococci or streptococci, blood cultures are consistently positive if the patient has not been on antimicrobial therapy.

If cardiac complications such as a new or changing murmur arise, indicating the possibility of a paravalvular leak or ring dehiscence, urgent if not emergent operative débridement and replacement are advised. Treatment strategies from an antimicrobial perspective are somewhat more aggressive in PVE than NVE. Therapy should be chosen and tailored based on the identification and susceptibilities of the specific microorganism. If an organism is yet to be identified, vancomycin and gentamicin should be instituted empirically to cover *S. epidermidis*, *S. aureus*, and streptococci. The choice of antibiotics should also consider pathogens standardly encountered at the given hospital. Patients with PVE should be treated for 6 to 8 weeks in most cases, whether or not the valve is removed. If microorganisms are isolated at the time of valve replacement, an additional 6 to 8 weeks of therapy beginning at the time of organism isolation should be instituted.⁸⁴

SUMMARY

NVE and PVE remain significant causes of morbidity and mortality, although recent developments in antimicrobial agents, diagnostic tools, and surgical techniques have improved the prognosis for patients affected by

these diseases. Early detection combined with aggressive antibiotic therapy and early surgical intervention can successfully treat most cases of NVE and PVE. Notable challenges for the cardiac surgeon include the determination of the appropriate timing of operation, removal of all infected tissue, and restoration of physiologic valve function, but sound clinical judgment and meticulous surgical technique can allow for safe and effective surgery.

ANTICOAGULATION, THROMBOSIS, AND THROMBOEMBOLISM OF PROSTHETIC CARDIAC VALVES

Joseph C. Cleveland, Jr. • Frederick L. Grover

CHAPTER OUTLINE

ARTIFICIAL SURFACES, COAGULATION CASCADES, THROMBOSIS, AND LYSIS

ANTICOAGULATION THERAPY

COMPLICATIONS OF ANTICOAGULATION

Warfarin Sodium

Heparin Sulfate System

Direct Thrombin Inhibitors and Factor Xa Inhibitors

Antiplatelet Agents

PROSTHETIC HEART VALVES

Prosthetic and Mechanical Heart Valves and Thromboembolism

Bioprosthetic Valves and Thromboembolism

Management of Prosthetic Valve Thrombosis

ARTIFICIAL SURFACES, COAGULATION CASCADES, THROMBOSIS, AND LYSIS

Intravascular placement of a foreign body with its non-endothelial surface activates the clotting mechanism, leading to thrombus formation. The exposure of blood to the synthetic surface leads rapidly to deposition of a fine layer of plasma components, mostly protein, followed by platelet deposition. The intrinsic coagulation cascade is initiated along with the extrinsic coagulation cascade: the inflammatory response, including leukocyte activation; the complement system; and fibrinolysis.

Fibrinogen is one of the major plasma proteins, often the first that is deposited on these artificial surfaces. Once the layer of fibrinogen is absorbed onto the surface, platelets can adhere to the fibrinogen. Although surfaces vary greatly in their tendency to promote thrombosis, the reactivity of most materials to blood can be significantly increased if they are first exposed to fibrinogen.¹ Other proteins also are deposited, including fibronectin (a surface protein of many cells), von Willebrand factor (a glycoprotein essential for the adhesion of platelets to subendothelial tissue), thrombospondin (a platelet protein secreted by activated platelets), and factor XII (Hageman factor, the primary activator of the intrinsic coagulation system).

Once platelets attach to the protein layer and spread out on the artificial surface, materials present in the platelet intracellular granules are secreted, including

β -thromboglobulin, which inhibits prostacyclin production; platelet factor 4, which neutralizes heparin sulfate in the endothelium; and serotonin, adenosine triphosphate (ATP), and adenosine diphosphate (ADP). Synthesis of prostaglandins E and F is evident as well, suggesting that endoperoxide metabolism has taken place along with formation of thromboxane A₂ from platelet arachidonic acid. Serotonin, thromboxane A₂, and endoperoxide are potent vasoconstrictors and platelet stimulatory factors.² Finally, platelet aggregation follows platelet adhesion, probably by ADP and serotonin secretion from the adherent platelets. Fibrinogen and thromboxane A₂ are key in this step.

The coagulation cascade is initiated either by reaction of plasma proteins with the artificial surface to form enzymatically active components such as factor XII (intrinsic system) or by introduction of thromboplastin through exposure of subendothelial tissue to the surface (extrinsic system). [Figure 83-1](#) is a schematic diagram of the clotting cascade. Activation of factors XIIa and XIa initiates the intrinsic system, leading to activated factor Xa. Platelets provide the phospholipid surface for this reaction. Activated factor XIIa also initiates the kininogen-kallikrein system, and kallikrein provides positive feedback for the contact activation. Kallikrein cleaves factor XII to convert it to factor XIIa, thereby accelerating contact activation. Bradykinin is also released when kallikrein cleaves high-molecular-weight kininogen. Activated high-molecular-weight kininogen can then bind more prekallikrein and factor XI to the activating surface,

Surface activation

FIGURE 83-1 ■ The coagulation cascade from surface activation to the final common pathway. *HMWK*, High-molecular-weight kininogen; *pl*, phospholipid. (From Ware JA, Lewis J, Salzman EV: Antithrombotic therapy. In Rutherford RB, editor: *Vascular surgery*, ed 3, Philadelphia, 1989, Saunders.)

which further increases the reaction. In the final common pathway, prothrombin is converted to thrombin, and fibrinogen is converted to fibrin. Thrombin recruits more platelets, creating more adhesion and aggregation. A fibrin platelet clot is formed, and thrombosis occurs.

Activation of the clotting cascade on the surface of an artificial device occurs similarly whether it is on the cardiac valve, cardiopulmonary bypass system, vascular graft, extracorporeal membrane oxygenation (ECMO) circuit, mechanical assist device, or vascular catheter. It will produce thrombus formation, and macroscopic and microscopic platelet-fibrin emboli occur commonly as well. Factor XII, kallikrein, and plasmin activate the complement system and activate neutrophils, and kinin formation mediates vasodilation, vascular permeability, and white blood cell migration. Normally, a delicate balance is maintained between these two systems so that uncontrolled clotting or hemorrhage does not occur. The coagulation cascade is initiated, and factor XII and kallikrein initiate clot lysis with conversion of plasminogen to plasmin. Antiplasmins in the circulating blood, particularly α_2 -antiplasmin, rapidly neutralize most of the circulating plasmin; however, plasmin also is incorporated into the clot during clot formation. The fibrin meshwork protects plasmin from antiplasmin once the

FIGURE 83-2 ■ The vitamin K cycle in the formation of the vitamin K-dependent clotting factors. Vitamin K enters the body and is reduced to vitamin K_1H_2 . K_1H_2 and carboxylase convert vitamin K-dependent clotting factor precursor proteins into active factors; epoxidase converts vitamin K_1H_2 to vitamin K_1 -epoxide (K_1O). Reduced vitamin K_1H_2 is regenerated by reduced nicotinamide adenine dinucleotide (NADH) and is the warfarin-sensitive step. CAD, Coumarin-type anticoagulant drugs. (From O'Reilly RA: Therapeutic modalities for thrombotic disorders: vitamin K antagonists. In Coleman RW, Hirsh J, Marder VJ, et al, editors: *Hemostasis and thrombosis: basic principles and clinical practice*, ed 2, Philadelphia, 1987, Lippincott Williams & Wilkins.)

plasmin is activated to plasmin, allowing fibrin degradation in the clot. In fact, many natural inhibitors offset activated procoagulant protein. Protein C, heparin, antithrombin III, protein S, thrombomodulin, prostacyclin, and plasmin all counter steps in the coagulation cascade.³

ANTICOAGULATION THERAPY

Clinically useful drugs that block the clotting cascade fall into the following primary groups: orally administered vitamin K antagonists; natural anticoagulants, such as the heparin-antithrombin III system; direct thrombin inhibitors, antiplatelet drugs, factor Xa inhibitors; and fibrinolytic agents.

Warfarin sodium remains the most popular orally administered vitamin K antagonist used today in the United States. It blocks the formation of the four vitamin K-dependent clotting factors (prothrombin and factors VII, IX, and X), creating a buildup of their precursors. Warfarin sodium blocks the vitamin K cycle at the regeneration of reduced vitamin K, which is the active form of vitamin K (Fig. 83-2).

Heparin's anticoagulant effect is fairly complex and not completely understood. Heparin sulfate is a glycosaminoglycan that binds to antithrombin III and activates this serine protease inhibitor. Heparin and antithrombin III occur naturally in humans, are secreted by endothelial

cells, and are required to produce their anticoagulant effect. Antithrombin III binds to thrombin and blocks the enzymes of the intrinsic coagulation cascade, including thrombin and factors IXa, Xa, XIa, and XIIa. Both unfractionated heparin and low-molecular-weight heparins work via the previously mentioned mechanisms.

Direct thrombin inhibitors and factor Xa inhibitors have emerged as alternative agents to warfarin for oral anticoagulation. Dabigatran is an orally administered direct thrombin inhibitor, whereas rivaroxaban and apixaban are factor Xa inhibitors. Dabigatran received U.S. Food and Drug Administration (FDA) approval for prevention and treatment of venous thromboembolic disease and treatment of nonvalvular atrial fibrillation based primarily on data from the RE-LY trial.⁴ Several intravenous direct thrombin inhibitors exist, including lepirudin, desirudin, argatroban, and bivalirudin. These agents are used primarily as alternatives to heparin when heparin-induced thrombocytopenia is suspected or confirmed with appropriate diagnostic studies.

Rivaroxaban is an orally administered competitive, direct factor Xa inhibitor. Noteworthy is that this agent is contraindicated in patients with creatinine clearance of less than 15 mL/min or patients on hemodialysis. Rivaroxaban was studied in the ROCKET-AF trial and found to be non-inferior to warfarin in the prevention of stroke in patients with atrial fibrillation.⁵ This agent also was studied for prevention of venous thromboembolism (VTE) during orthopedic surgery and showed efficacy.⁶

The various antiplatelet drugs have different mechanisms of action, making them more or less useful as therapeutic anticoagulation agents. Figure 83-3 is a schematic diagram of the actions of antiplatelet drugs. Aspirin inhibits platelet aggregation by irreversible acetylation of platelet cyclooxygenase, hence blocking the synthesis of prostaglandins and thromboxane A₂. Aspirin prolongs the bleeding time, although variable responses to aspirin's anticoagulant effect exist. Aspirin inhibits platelet aggregation for the life span of the platelet, which is typically 7 to 10 days.

Four adenosine diphosphate P2Y₁₂ (ADP P2Y₁₂) receptor antagonists are FDA approved. These agents reduce platelet aggregation mediated by the binding of fibrinogen to activated glycoprotein (GP) IIb/IIIa receptors on platelets. The thienopyridines are in widespread use as potent antiplatelet agents and are typically used in dual antiplatelet therapy following percutaneous coronary intervention. Clopidogrel in vitro does not affect platelet aggregation. However, in vivo, clopidogrel is metabolized by the liver to several active metabolites—with these metabolites irreversibly inhibiting the P2Y₁₂ platelet receptor. Clopidogrel supplanted ticlopidine principally because ticlopidine is associated with aplastic anemia and thrombotic thrombocytopenic purpura.⁷ The thienopyridine prasugrel converts to active metabolites more efficiently than does clopidogrel; as such, the bleeding risk with this agent is increased compared with other agents in this class. Lastly, ticagrelor is a novel thienopyridine that directly antagonizes the P2Y₁₂ receptor. This drug is also reversible in its inhibition of the receptor. However, it requires twice-daily dosing in contrast with the other thienopyridines. It is presently a Class I

recommendation to discontinue all P2Y₁₂ inhibitors before cardiac surgery. The exact duration in days of discontinuation cannot be specified as the safe interval between discontinuation and cardiac surgery is unknown.⁸ In general, the range for cessation is between 3 and 7 days.

Dipyridamole is a reversible platelet agent, a weak vasodilator, and a weak inhibitor of the enzyme phosphodiesterase, which degrades cyclic adenosine monophosphate (cAMP) to 5'-AMP. With this block, more cAMP is available to inhibit platelet aggregation. Sulfapyrazone appears to reversibly block platelet prostaglandin synthesis and is another fairly weak anticoagulant. At clinical dosages, neither dipyridamole nor sulfapyrazone prolongs the bleeding time.

Finally, fibrinolytic therapy has a small but definite place in the management of thrombosis of artificial devices. Streptokinase and urokinase act similarly and induce rapid thrombolysis by activating plasminogen and subsequently forming plasmin. Plasmin causes degradation of the fibrin, reducing thrombus size. Unfortunately, streptokinase and urokinase also induce a generalized plasma proteolytic state as well as local fibrin degradation in the thrombus, and this can lead to uncontrolled hemorrhage. Newer agents (second-generation plasminogen activators) such as recombinant tissue plasminogen activator were developed to prevent induction of this generalized plasma proteolytic state by making these agents fibrin specific. However, this function appears to depend on the dose, and clinical use has not confirmed the decrease in potential for hemorrhage that was hoped for with these drugs.

COMPLICATIONS OF ANTICOAGULATION

Warfarin Sodium

Bleeding is the most common and most significant complication encountered with the use of warfarin, and therefore close monitoring of the prothrombin time is mandatory. Excessive amounts of warfarin that increase the prothrombin time beyond 2.5 times control and the international normalized ratio (INR) above 5 will increase bleeding complications four to eight times. The gastrointestinal tract is the site of most bleeding complications and is often associated with preexisting disease states, such as peptic ulcer, gastritis, genitourinary lesions, cancer, and hypertension. Indeed, based on the increase in dispensed prescription for warfarin rising by 45% from 1998 to 2004, warfarin is now among the top 10 drugs in the United States with the highest number of serious adverse event reports. Data submitted to the FDA and from a study auditing U.S. death certificates suggest that major bleed frequencies for warfarin are as high as 10% to 16%.⁹

Another significant complication of initial warfarin therapy is skin necrosis. This is secondary to a temporary hypercoagulable state induced in the capillaries when the concentration of protein C (a natural vitamin K-dependent and warfarin sodium-sensitive anticoagulant that circulates in the blood) falls before warfarin's

A

ATP, Adenosine triphosphate; EPA, eicosapentaenoic acid; LMW, low molecular weight; PG, prostaglandin. (**A**, From Stein B, Fuster V, Israel DH, et al: Platelet inhibitor agents in cardiovascular disease: an update. *J Am Coll Cardiol* 14:813–836, 1989. Reprinted with permission of the American College of Cardiology. **B**, Reprinted with permission from the Institute for Continuing Healthcare Education: *The rationale for extended antithrombotic therapy for patients with post-acute coronary syndromes*.)

inhibition of factors II, IX, and X becomes effective and the desired hypocoagulable state occurs. The activated form of protein C is a powerful inactivator of factors V and VIII. Why this is limited to the skin is unknown.¹⁰ When warfarin is used in pregnant women, it can cause embryopathy in 4% to 8% of fetuses exposed in the first trimester, and exposure to warfarin in the second and third trimesters causes central nervous system abnormalities in 3% of pregnancies. Finally, prematurity, fetal hemorrhage, and stillbirth are increased in infants exposed to warfarin.^{11,12} For these reasons, bioprostheses or allografts should be placed, when possible, in women of childbearing age.

Heparin Sulfate System

Again, the most common complication of heparin therapy is bleeding. Hemorrhagic complications occur in 10% to 20% of patients with normal hemostasis and in up to 50% of patients with thrombocytopenia or uremia.¹³ Thrombocytopenia has been reported in up to 31% of patients and can cause significant morbidity and mortality when it is associated with platelet clumping and thrombosis. Heparin-induced thrombocytopenia (HIT) has become an increasingly recognized and important clinicopathologic syndrome. The frequency of HIT among patients exposed to heparin is highly variable and related to the type of heparin, the patient population, the duration of heparin exposure, and the patient's sex.¹⁴ The immunoglobulin G antibodies form a complex against platelet factor 4/heparin, which binds to the platelet Fc receptor, leading to platelet aggregation and release of prothrombotic microparticles. Cardiac surgery patients are prone to formation of anti-platelet factor 4/heparin antibodies. Accordingly, if the platelet count falls by more than 50% between postoperative days 5 and 14, investigation for HIT antibodies should occur. If HIT is suspected or diagnosed, a direct thrombin inhibitor (lepirudin, bivalirudin, or argatroban) should be initiated and continued until the platelet count normalizes. It is imperative that all sources of heparin be stopped if HIT is suspected. This includes removal of a pulmonary artery catheter if it is heparin coated. If further anticoagulation becomes necessary, such as cardiac reoperation, the surgeon can wait for the antibodies to become undetectable and reuse heparin.¹⁵ However, this may take up to 40 days. Another alternative is to use nonheparin anticoagulants such as danaparoid sodium, lepirudin, and argatroban.¹⁶ Platelet inhibition with glycoprotein IIb/IIIa antagonists followed by unfractionated heparins has also been used successfully.¹⁷

Fractions of heparin that display this effect have the least anticoagulant activity, so the use of low-molecular-weight heparin with high anticoagulant effect and low ability to lead to platelet clumping has become clinically more important.

Direct Thrombin Inhibitors and Factor Xa Inhibitors

Given the widespread adoption of orally available thrombin and Xa inhibitors, clinicians will encounter minor and

occasionally serious, life-threatening bleeding from these agents. The bleeding rates with dabigatran, rivaroxaban, and apixaban reported by various trials are generally 4% to 14%. Management of minor bleeding from these agents usually includes cessation of the agent. The period of time required for cessation of these agents before major procedures is unknown, but a minimum of 5 to 7 days without the drug before a cardiac operation seems prudent. The management of severe, life-threatening bleeding from these agents is challenging because no direct reversal agents are available. In general, to stop major or life-threatening bleeding related to one of these agents, nonactivated prothrombin complex concentrate (PCC) has been recommended.¹⁸

Antiplatelet Agents

Antiplatelet therapy is the mainstay of treatment for coronary artery disease. In some cases, patients require urgent cardiac operations while on these medications. Aspirin does not seem to confer an unduly increased risk for bleeding. The data for clopidogrel suggest that for patients undergoing cardiac surgery within 5 days from the last dose, increased bleeding can be anticipated.¹⁹

The data regarding the newer P2Y₁₂ agents and bleeding after coronary artery bypass graft (CABG) are still emerging. The TRITON-TIMI 38 trial examined prasugrel in comparison with clopidogrel for acute coronary syndromes. Although only 437 patients of 13,608 in this study underwent CABG after receiving either prasugrel or clopidogrel, the rates of minor and major bleeding with prasugrel were 14.1% versus 4.5% in the clopidogrel group.²⁰ Based on these data, it would be prudent to wait 7 days before embarking on a cardiac operation after the last dose of prasugrel if possible. If unable to wait, it is suggested that platelet transfusions can be effective in dealing with bleeding if there has been at least 12 hours between the last dose of prasugrel and the platelet transfusions.²¹ With regard to ticagrelor and bleeding after cardiac surgery, there are insufficient data to base firm decisions. There are little data supporting management of post-CABG bleeding with this agent. It would seem prudent to wait a minimum of 5 days before undergoing cardiac surgical procedures in this group. The latest Society of Thoracic Surgeons Guideline Statement regarding this subject gives credence to the idea of testing platelet inhibition rather than waiting an arbitrary amount of time.⁸

PROSTHETIC HEART VALVES

Edmunds and coworkers^{22,23} and Cohn²⁴ have detailed the need for standardized reporting of thrombotic complications, including uniform definitions; stratification of the data to include the severity of the event, including death; and careful, complete long-term follow-up. Without this standardization, it is difficult to make accurate statements about results, complications, and appropriate anticoagulation therapy. Similarly, it is difficult to compare valves placed in the 1960s and 1970s and their associated complications with valves placed in later decades and their complications.

Through the years, bioengineering advances have led to fewer thrombogenic materials, such as carbon Pyrolite for the St. Jude valve, and a better mechanical valve design has decreased the incidence of valve thrombosis and thromboembolism through greater central flow characteristics. However, more effective anticoagulation has been the most important factor for the decreased incidence of thrombosis in the 1980s and 1990s compared with the 1960s and 1970s, particularly with mechanical valves. Bioprosthetic valves have less inherent thrombogenicity, but this is a result of better central flow characteristics, flexible leaflets, and sinusoidal washout rather than true thromboresistance of the preserved tissue.²⁵ At present, stented porcine xenograft valves and pericardial valves are in use as tissue bioprostheses. The major problem with the pericardial xenograft valves was their durability; both valves developed tearing of the cusps secondary to stress after only a few years of use. The pericardial valves used today are much better and tend to fail by calcification.²⁶

Most prosthetic valves have a sewing ring that is covered with a Dacron or Teflon cloth. When this is exposed to the blood, an adherent layer of thrombus is laid down and serves as a blood-compatible coating. It is initially thin and delicate but later becomes invaded by well-vascularized fibrous tissue. This resists further formation of thrombus. However, if the flow pattern is abnormal, this tissue ingrowth can creep into the orifice from below the valve-sewing ring, forming an obstructive pannus. Finally, allograft aortic valves and pulmonary valved conduits have almost normal platelet survival time and do not form thrombi.

Prosthetic and Mechanical Heart Valves and Thromboembolism

Determining the risk of thromboembolism for patients who undergo mechanical valve replacement is subject to various complex patient- and prosthesis-related factors. A few general principles apply, however. Data from early small case series in which patients were followed who had contraindications to vitamin K antagonists support major thromboembolism rates of 4.0 per 100 patient-years to more than 8.6 per 100 patient-years for total embolic rates.²⁷ The data regarding optimal INR targets for mechanical aortic and mitral valves were derived from retrospective observational studies.²⁸ In general, mechanical valves in the mitral position have roughly 1.5 to 2 times the thromboembolic risk over mechanical valves in the aortic position. Both the American College of Cardiology/American Heart Association (ACC/AHA) and the European Society of Cardiology maintain guideline-supported recommendations for target INR with both mechanical and bioprosthetic valves.^{29,30}

The incidence of all thrombotic complications, including thromboembolic events, for a mechanical aortic prosthesis is approximately 1% to 2% per patient-year, whereas the rate for bioprosthetic valves in the aortic position is approximately half that of the mechanical prostheses.³ The risk of bleeding complication is, however, generally accepted to be higher for mechanical valves in the aortic position versus bioprosthetic valves

because of the use of warfarin anticoagulation. In the two large randomized trials that compared outcomes for patients with either a mechanical or porcine heart valve, both the Edinburgh Heart Trial and the Veterans Affairs Cooperative Trial showed a higher rate of bleeding with mechanical valves.^{31,32}

Bioprosthetic Valves and Thromboembolism

The rate of thromboembolic events for patients with bioprosthetic valves is thought to be highest during the first 90 days after implantation. Specifically, this rate is highest for the first 10 days after aortic valve implantation for the aortic position in patients without warfarin anticoagulation. The thromboembolic rate for a bioprosthetic valve is also high for the mitral position in patients without anticoagulation for days 1 through 10 and for days 11 through 90.³³ Based on these data, it became common practice for patients who received either an aortic or a mitral bioprosthesis to receive 3 months of vitamin K antagonist anticoagulation.

This practice of routinely anticoagulating bioprosthetic valves in the aortic position has been revisited. ElBardissi and colleagues studied 861 patients who underwent bioprosthetic aortic valve replacement. Of these 861 patients, 133 patients (15%) received warfarin anticoagulation and 782 (85%) did not. No difference in thromboembolic events was found between the two groups.³⁴ However, a large Danish registry study recently established a very high thromboembolic rate for patients without warfarin anticoagulation: 7.00 per 100 patient-years versus 2.69 per 100 patient-years in patients treated with warfarin anticoagulation for the first 90 days after bioprosthetic aortic valve replacement.³⁵ Based on current evidence-based guidelines, the 2014 ACC/AHA guidelines suggest that it is a Class IIb recommendation for warfarin administration for 3 months following implantation of a bioprosthetic valve in the aortic position. It should be noted that it remains a IIa recommendation regarding warfarin administration for patients who receive bioprosthetic valves in the mitral position.²⁹

Hammermeister and the Veterans Affairs Cooperative Study on Valvular Heart Disease³² concluded that after 15 years, the rates of survival for patients receiving a mechanical aortic valve replacement were higher than those for patients receiving a bioprosthetic aortic valve replacement. For patients receiving mitral valve replacement, there were no differences in survival rates between patients receiving mechanical valves and those receiving tissue valves. The improved survival rate in the mechanical aortic valve replacement group was offset by a higher rate of bleeding. Structural failure, however, was observed only with the bioprosthetic valves, and bleeding complications were statistically more frequent among patients who received mechanical valves. Hammond and associates,³⁶ in a study of 1012 adult patients who underwent placement of either a mechanical valve or a bioprosthesis with a follow-up of 4814 patient-years, found little direct evidence to strongly support the generalized use of one type of valve over another.

Unfortunately, bioprostheses have a very high failure rate in children, probably because of accelerated calcium metabolism, and there is currently a renewed interest in the use of both fresh and commercially available frozen allograft valves for children and young adults to prevent anticoagulation. The risk of thrombotic or thromboembolic events with use of allograft aortic valves in the subcoronary position, as a free-sewn graft or by root replacement in which a cylinder including the valve is placed by the technique of Ross,³⁷ is almost zero without anticoagulation. Matsuki and coworkers³⁸ reported on 555 consecutive hospital survivors who underwent isolated aortic valve replacement with a free-sewn allograft. The incidence of thromboembolism was 0.034% per patient-year, or 1 patient of the 555 studied. Results with the aortic root replacement in 108 patients described by Okita and associates³⁹ showed no incidence of thromboembolism in 180 patient-years of follow-up. Penta and colleagues⁴⁰ similarly found no incidence of thrombosis or thromboemboli in 140 consecutive patients who underwent homograft replacement of the aortic valve and were observed for a minimum of 10 years. Many of these valves were either fresh or antibiotic-preserved valves. O'Brien and associates⁴¹ reported on a comparison of aortic valve replacements with viable cryopreserved and fresh allograft valves. The freedom from thromboembolism for both groups was 97% at 10 years and 96% at 15 years; the reoperation rate for valve failure was much higher in the group that received the fresh valves. O'Brien initially believed that cryopreserved valves were superior because fibroblastic cell viability is preserved, providing durability. However, recent developments have pointed toward an immunologic basis for valve deterioration with live cells.

The fate of the aortic valve or pulmonary valve used as a conduit to reconstruct the right ventricular outflow tract is not as clear. Bull and associates⁴² described 249 patients who received extracardiac conduits in the right side of the heart. Of the 173 patients who survived 30 days, 72 underwent placement of xenograft conduits of various types, and 4 underwent placement of valveless tubes. The complication and reoperation rates for both valved conduit groups were similar. Calcification of the allograft tube occurred commonly, but the obstruction tended to be at the proximal portion of the conduit where Dacron extensions, which are circumferential, were commonly placed. The development of the neointimal peel in this position led to the obstruction in more than two thirds of patients.

If a noncircumferential proximal hood is used, thrombus and neointimal peel formation is minimal, and obstruction is markedly decreased. Livi and associates⁴³ have shown that the valve of choice for right ventricular outflow tract reconstruction is, in fact, the pulmonary allograft rather than the aortic allograft. Finally, Matsuki and associates⁴⁴ have used the pulmonary autograft valve (the patient's own pulmonary valve) to replace the aortic valve with excellent results (Ross procedure). However, this procedure requires the reconstruction of the right ventricular outflow tract with a pulmonary or aortic allograft, essentially giving the patient disease of two valves rather than the one-valve disease the patient had

originally. Despite this, Matsuki and associates⁴⁴ have shown excellent results with this technique. Finally, the Contegra bovine valved jugular vein seems to be a good alternative for pediatric right ventricular outflow tract reconstruction.

Several general rules make some clinically applicable sense out of these sometimes conflicting data. For children, aortic valve replacement should be carried out either with a mechanical valve, such as the St. Jude bileaflet valve, or with the pulmonary autograft technique to replace the aortic valve as described by Ross in 1967.⁴⁵ This has become the method of choice for aortic valve replacement in children. For mitral valve replacement in children, mechanical valves are required, and these patients should undergo full anticoagulation with warfarin and aspirin. Xenograft bioprostheses should not be used because of the rapid calcification and degeneration that occur with these valves in children. Similar guidelines should be followed for young adults. For women who are of childbearing age or wish to have children, mechanical valves should be strongly discouraged. The complications of anticoagulation, particularly with warfarin sodium and heparin, place the young woman and unborn child at too great a risk. For non-childbearing women and for men younger than 60 years, individual differences in the patients and their desired lifestyle after valve replacement should be strongly considered in choosing the valve. Finally, probably for patients older than 60 years but definitely for those older than 70 years, the use of xenograft bioprostheses (stented or stentless) should be strongly considered in view of the decreased degeneration rate of these valves in older patients and the higher risk of anticoagulation in this population of patients. Guideline-supported recommendations regarding choice of mechanical or bioprosthetic valves support a patient-centered approach to discussing the risks and benefits of prosthetic valve options.²⁹

Management of Prosthetic Valve Thrombosis

All prosthetic valves, including bioprostheses, can develop thrombotic occlusion, but the incidence is higher for the mechanical valve, specifically the caged ball valve and the tilting disc valve. The thrombosis is usually more acute, manifesting as "sudden" valve dysfunction with clinical shock, pulmonary edema, and loss of valve click sounds in mechanical valves and muffled sounds in bioprostheses. The diagnosis is made by fluoroscopy or two-dimensional transthoracic echocardiography, or both. Mortality is high without either fibrinolytic therapy or reoperation. The incidence of this complication is less than 0.3 per 100 patient-years, except for the Omniscience tilting disc valve placed in the mitral position, which has a significantly higher incidence of thrombosis.³

With regard to management of a suspected thrombosis of a left-sided prosthetic heart valve, determination of whether the thrombus is obstructive based on imaging studies is the initial priority. If the thrombus is obstructive and the patient is critically ill, then surgical replacement of the prosthesis is warranted unless the patient is deemed too high risk for operation because of comorbid

conditions. It is arguably difficult to determine which patient or subset of patients is too high risk, because the operative mortality rate approaches 15% and all cases of prosthetic valve thrombosis are therefore “high risk.” Based on the limited data set, the following therapeutic strategies are suggested: thrombolysis is reserved as the initial strategy for patients in NYHA Class I/II heart failure, if surgery is not available (e.g., patient is in a location without cardiac surgery and too unstable to transport), the patient refuses surgery, or if the thrombus is nonobstructive and small (<0.8 cm²). Almost all right-sided prosthetic valve thromboses can be treated with lytic therapy initially, and surgery used if thrombolysis is unsuccessful.⁴⁶

FUTURE SYSTEMS AND NOVEL VISUALIZATION TECHNIQUES

CONCLUSION

Cardiac surgery has traditionally been performed through a complete median sternotomy, which provides generous operative exposure to all structures in and around the heart. With this approach, complex cardiovascular procedures can be performed safely and effectively. Reductions in incision size and tissue manipulation became possible with the advent of closed-chest cardiopulmonary techniques and advances in instrumentation. Improvements in intracardiac visualization and robotic telemanipulation have pushed the bounds even further.

Today, robotic cardiac surgery, particularly valve surgery, has become standard practice for some surgeons. In this chapter, we describe our experience with robotic mitral valve surgery and other minimally invasive approaches. A number of future systems and novel visualization techniques that might enhance future robotic systems are outlined as well.

ROBOTIC SYSTEMS

Three-dimensional vision and seven degrees of freedom are optimal to manipulate and freely orient objects in a three-dimensional space, such as a body cavity. Consequently, standard endoscopic surgery with only two-dimensional vision and four degrees of freedom reduces accuracy, efficiency, and dexterity of movement. Human motor skill, specifically eye-hand coordination, deteriorates with the indirect observation and manipulation of instruments and tissues in endoscopic surgery. In addition, instrument shaft shear, or drag, necessitates higher manipulation forces by the surgeon, leading to hand muscle fatigue. The surgeon must reverse hand motions in endoscopic surgery because the fixed entry point (fulcrum effect), such as a trocar, makes it a motor skill

set that is nonintuitive to learn. Computer-enhanced systems have been developed to overcome these and other limitations. Through telemanipulation, the surgeon operates from a console with a three-dimensional view of the operative field. The surgeon's movements are reproduced in a scaled proportion by instruments mounted on robotic arms inserted through the chest wall. The robotic arms and "micro-wrist" instruments mimic the human arm and wrist with seven full degrees of freedom. For cardiac surgery, a robotic telemanipulation system, the da Vinci Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA), is currently available, with two different versions.

The da Vinci S Surgical System has three components: a surgeon console, a patient-side cart, and a vision cart. The surgeon console is separated physically from the patient and allows the surgeon to sit ergonomically with his or her head positioned in a three-dimensional vision system, arms at the side, and hands beneath the vision system. This natural eye-hand-instrument alignment replicates the experience of open surgery. The surgeon's analog finger and wrist movements, along with any tremor, are converted to digital signals by sensors in the console. The movements are scaled, whereby movements of the surgeon at the console are larger than movements of the instruments in the patient. The tremors are filtered and smoothed, which removes inherent human tremor with a frequency of 8 to 10 Hertz. This motion scaling and tremor suppression enhance precision at the tissue level. A clutching mechanism at the console, which temporarily disconnects the surgeon's and instruments' movements, enables readjustment of hand positions to maintain optimal ergonomics. The surgeon's movements are transferred to the patient cart digitally, where the instruments move synchronously through one of the four

independent effector arms. For cardiac surgery, the arms are used to control the camera, the surgeon's left and right hands, and the atrial retractor. The vision cart houses the image-processing equipment and a large viewing monitor, which provides the operating room team, including the patient-side assistant, a view of the operative field. The three-dimensional vision system facilitates natural depth perception with high-power magnification (10×) via both 0-degree and 30-degree endoscopes.

The da Vinci *Si* Surgical System, the most recent version, incorporates dual-console capability, enhanced three-dimensional 1080i high-definition visualization, an updated user interface, and improved operating room integration. The dual-console feature supports training and collaboration by allowing two surgeons to sit at separate consoles and easily and quickly take control of the instruments at any time during surgery. Three-dimensional high-definition visualization with capability of 10× magnification increases viewing resolution, providing improved clarity and detail of the anatomic structures. The updated user interface with easy-to-use touchscreen controls simplifies intraoperative system and vision adjustments. Addressing the increasing trend toward operating room integration, vision system components traditionally housed in the vision cart can be installed on an operating room boom, and a multiple-input display allows viewing of up to three video sources, such as the operative field, ultrasound, and electrocardiogram (ECG), at one time.

EVOLUTION OF ROBOTIC CARDIAC SURGERY

Initially, advances in minimally invasive surgery were based on modifications of previously used approaches performed under direct vision. Mini-sternotomies, partial sternotomies, parasternal approaches, and mini-thoracotomies simply reduced the size of the incisions and the degree of tissue manipulation.¹⁻⁴ Advances in cannulation methods and video-optics opened the door for totally endoscopic robotic surgery.

The introduction of Port-Access technology (Cardio-vations, Inc., Ethicon, Somerville, NJ) in 1996 combined a minimally invasive surgical approach (nonsternotomy) with total cardiopulmonary bypass and an arrested heart.^{5,6} The system provides extrathoracic cardiopulmonary bypass with a specialized set of endovascular canulas and catheters to provide antegrade or retrograde cardioplegic arrest, and ventricular decompression. Encouraging results confirmed the feasibility and safety of these techniques and paved the way for the development of less invasive operations. Advances in video-optics started a wave of new endoscopic approaches in general, urologic, gynecologic, and orthopedic surgery. Video assistance in cardiac surgery was first used for closed chest internal mammary artery harvests and congenital heart operations.⁷⁻⁹ In 1996, Carpentier and colleagues performed the first video-assisted mitral valve repair using ventricular fibrillation via a mini-thoracotomy.¹⁰ Soon thereafter, Chitwood and coworkers performed a

video-assisted mitral valve replacement using a microincision, percutaneous transthoracic aortic clamp, and retrograde cardioplegia.¹¹

Cardiac surgery entered the robotic age in 1997 when Mohr first used the AESOP (Intuitive Surgical, Inc., Sunnyvale, CA) voice-activated camera robotic arm in mitral valve surgery. In addition to freeing up the surgeon's hands during surgery, this device allowed for better valve and subvalvular visualization with even smaller incisions.¹² In 1998, Chitwood performed the first video-directed mitral operation in the United States, using the voice-controlled AESOP 3000 robotic arm and a Vista three-dimensional camera (Vista Cardiothoracic Systems, Inc., Westborough, MA).¹¹ The combination of robotic camera control and three-dimensional visualization was an essential step toward the totally endoscopic mitral operations performed today. The first mitral valve repair using an early prototype (the da Vinci articulated intra-cardiac wrist robotic device) of the present da Vinci robot was done by Carpentier and colleagues in 1998.¹³ The first complete repair in North America using the da Vinci system was performed by Chitwood and colleagues in 2000.¹⁴ A 4-cm incision was used for assistant access, but advancements in three-dimensional video and robotic instrumentation progressed to a point where totally endoscopic procedures were feasible. Lange and coworkers performed the first totally endoscopic mitral valve repair using only 1-cm ports with the da Vinci in 2000.¹⁵

In contrast to mitral valve surgery, closed-chest (non-sternotomy) coronary artery bypass surgery could be performed only after the robotic telemanipulation system had been developed. Technically complex maneuvers, such as coronary anastomosis, could not be done with conventional thoracoscopic instruments because dexterity was lacking. Freedom of movement with the "endowrist" instruments, where additional articulation occurs within the patient near the tip of the instrument, was critical in achieving this goal. Early reports of success originated from several centers that were pioneering the effort.¹⁵⁻¹⁸ Although robotic coronary surgery has gained less traction than mitral surgery, today it can be performed safely with reproducible results at dedicated centers.^{19,20}

CLINICAL APPLICATIONS AND PATIENT SELECTION

The da Vinci robot is used for mitral valve repair and single-vessel coronary artery bypass. It is less frequently used for mitral valve commissurotomy and tricuspid valve repair. In our experience, patients are offered robotic mitral valve surgery if they meet strict criteria ([Box 84-1](#)). Patients who have coronary artery disease or other valvular disease that would warrant surgery are excluded. Although tricuspid valve repair and coronary artery bypass graft surgery can be done using a robotic approach, the port placement and patient positioning are different. Mild aortic regurgitation (1+) or greater is also a contraindication because of the inability to reliably arrest the heart with retrograde cardioplegia alone. Patients with a prior sternotomy or right thoracotomy, or who have

BOX 84-1 Robotic Mitral Surgery Exclusion Criteria

- Coronary artery disease or other valvular disease requiring surgery
- Mild (1+) aortic regurgitation or greater
- Prior sternotomy or right thoracotomy
- Significant chest wall deformity that would limit access
- Severely calcified mitral valve annulus
- Aortic, iliac, or femoral atherosclerosis greater than minimal, or femoral vessels less than 7 mm (consider axillary artery cannulation)

significant chest wall deformities that would limit access, are also excluded in our current practice, although there is some early experience with operations on such patients at other centers. Patients with a severely calcified mitral annulus are not candidates because decalcification requires further refinement of instruments and a more reliable means of evacuating any calcium that falls into the ventricle. Lastly, aortic, iliac, or femoral atherosclerosis greater than minimal, and femoral vessel diameter less than 7 mm, are relative contraindications; however, in such cases axillary perfusion may be substituted for femoral artery perfusion.

SURGICAL TECHNIQUES

After induction of general anesthesia, the patient is intubated with a double-lumen endotracheal tube, and a transesophageal echocardiography (TEE) probe is placed. A retrograde coronary sinus catheter is placed via the internal jugular vein and positioned under echocardiographic guidance. Bilateral arterial lines are placed if endoaortic balloon technology is to be used for aortic occlusion and cardioplegia delivery. The patient is positioned with the right chest elevated 30 degrees with a roll caudal to the right scapula and arms tucked at the patient's side.

Subsequent steps should follow a well-defined order to minimize unnecessary morbidity if patient factors preclude a robotic approach and the approach needs to be converted. The femoral vessels are exposed through a small skin incision superior and parallel to the inguinal crease. Once the vessels are deemed appropriate for cannulation (size at least 7 mm and free of atherosclerosis), single left-lung ventilation is established and the robotic ports incisions are made. First, the camera port is placed in the fourth intercostal space 2 to 3 cm lateral to the midclavicular line, and a 30-degree, three-dimensional, high-definition camera is inserted. After inspecting the intrathoracic anatomy and planning the port placement for optimal visualization and repair of the valve, a 2-cm working port is made in the same interspace 2 to 3 cm lateral to the camera port. The left robotic arm port is placed in the third intercostal space 2 to 3 cm medial to the anterior axillary line. The right robotic arm port is placed in the fifth or sixth intercostal space just lateral to the anterior axillary line. The left atrial retractor port is

FIGURE 84-1 ■ Schematic (A) and photograph (B) of port placement for robotic mitral valve surgery. AAL, Anterior axillary line; MCL, midclavicular line.

placed through the fourth or fifth intercostal space just medial to the midclavicular line (Fig. 84-1).

A femoral venous cannula (22 or 25 Fr, Edwards Lifesciences, Irvine, CA) is positioned in the superior vena cava (SVC) under echocardiographic guidance, and in most cases a separate SVC cannula (17 Fr) is placed via the internal jugular vein over a wire. Arterial cannulation (19 or 21 Fr) is accomplished via the femoral artery (Fig. 84-2). Cardiopulmonary bypass is established at moderate hypothermia (32° C) and the pericardium is incised 2 to 3 cm anterior to the right phrenic nerve. In patients with a normal sized aorta (less than 4 cm), no evidence of atherosclerosis, and no aortic regurgitation, an aortic endoballoon is used for antegrade cardioplegia. Correct positioning is ensured by TEE and monitoring of bilateral upper extremity pressures. If an endoballoon is contraindicated, a separate antegrade cardioplegia catheter is inserted in the proximal aorta and a transthoracic aortic cross-clamp is positioned in the third intercostal space in the midaxillary line (Fig. 84-3). After cardioplegic arrest, a 3- to 4-cm left atriotomy is made medial to the right superior pulmonary vein, the atrial retractor is inserted in the atrium, and the atriotomy is extended to allow complete exposure of the mitral valve.

The surgeon performs the surgery at the console while the patient-side assistant changes instruments, changes supplies, and retrieves operative materials. Close

FIGURE 84-2 ■ Overview of cannulation showing femoral venous and arterial cannulas, retrograde coronary sinus catheter, and endoballoon.

FIGURE 84-3 ■ Transthoracic aortic cross-clamp and direct antegrade cardioplegia catheter.

inspection of the valve will determine what type of repair is required—leaflet resection and artificial chordae are the two most common techniques used to correct leaflet prolapse. Insertion of a partial flexible annuloplasty band using the running technique supports the repair and

FIGURE 84-4 ■ Schematic diagram of running annuloplasty suture technique using a partial flexible band. **A**, First suture is tied at right trigone and run clockwise to mid-portion of annulus. **B**, Second suture is tied at mid-portion of annulus and tails are tied to first suture. **C**, Second suture is run clockwise to left trigone. **D**, Third suture is tied at left trigone and tails are tied to second suture.

provides annular reduction (Fig. 84-4).²¹ Sutures to complete the repair are tied intracorporeally and retrieved by the patient-side assistant. Competency of the valve is tested by administration of antegrade cardioplegia and saline insufflation. The left atrium is closed using a running polytetrafluoroethylene (PTFE) suture. The robotic arms are removed, and standard de-airing and weaning procedures are performed under TEE. All patients have a transthoracic echocardiogram before discharge.

CLINICAL OUTCOMES

The world experience of robotic mitral valve surgery to date is mostly a collection of retrospective case series. Currently, only one large study exists that compares robotic mitral valve repair with alternative approaches. Nevertheless, surgical results thus far have been encouraging, and short-term outcomes appear similar to outcomes for repair using conventional approaches.

In 2000, Chitwood and colleagues completed the first phase I robotic mitral valve repair trial, which consisted of 10 patients.²² The average total arrest time and total operating room time were 150 minutes and 4.8 hours, respectively. There were no device-related complications and there was one reoperation for bleeding. Average postoperative length of stay was 4 days, and mitral regurgitation was trace or less for all patients at 3-month follow up. Based on these results, an extension of the trial was granted and subsequently reported in 2003 on 38 patients.²³ In this study, total operating room time decreased from 5.1 hours in the first group of 19 patients to 4.4 hours in the second group of 19 patients. Both cross-clamp and bypass times decreased significantly with experience as well. One patient underwent replacement for failed repair.

Mohr and coworkers described their initial experience in 2001 in 17 patients who underwent robotic mitral valve repair.²⁴ Conversion to an alternative approach was necessary in 3 of the 17 cases (17.6%). The average cross-clamp time was 89 ± 18 minutes. Intraoperative mitral regurgitation was trace or less in all but one patient who underwent an immediate endoscopic valve replacement. Another patient had postoperative failure before discharge and required replacement.

A multicenter phase II clinical trial involving 112 patients at 10 institutions was published in 2005.²¹ Total robot, aortic cross-clamp, and cardiopulmonary bypass times were 77.9 ± 0.3 minutes, 2.1 ± 0.1 hours, and 2.8 ± 0.1 hours, respectively. At 1-month echocardiographic follow-up, 9 patients (8%) had 2+ mitral regurgitation, and 6 (5.4%) of these had reoperations (5 replacements and 1 repair). There were no deaths, strokes, or device-related complications.

In 2006, Murphy and colleagues published their results of 127 robotic mitral valve operations.²⁵ Six of the 127 cases (4.7%) were converted to another approach. Of the 121 robotic surgeries, mitral valve repair was completed in 114 patients (94.2%), with the remaining 7 undergoing replacement. Mean aortic occlusion time (with endoaortic balloon) was 102 ± 28 minutes, and mean cardiopulmonary bypass time was 131 ± 34 minutes. Two patients (1.7%) required reoperation on the mitral valve, and there was one hospital death (0.8%). Echocardiographic follow-up was completed in 98 patients with a mean follow-up of 8.4 ± 8.1 months. Mitral regurgitation of trace or less was seen in 95 patients (96.9%).

Our initial results at Cleveland Clinic were published in early 2011.²⁶ From January 2006 to January 2009, 759 patients with degenerative mitral valve disease and posterior leaflet prolapse underwent primary isolated mitral valve surgery by complete sternotomy ($n = 114$), partial sternotomy ($n = 270$), right mini-antrolateral thoracotomy ($n = 114$), or a robotic approach ($n = 261$). Outcomes were compared on an intent-to-treat basis using propensity-score matching. Mitral valve repair was achieved in all patients except 1 patient in the complete sternotomy group. In matched groups, median cardiopulmonary bypass time was 42 minutes longer for robotic than complete sternotomy, 39 minutes longer than partial sternotomy, and 11 minutes longer than right mini-antrolateral thoracotomy ($P < 0.0001$); median myocardial ischemic time was 26 minutes longer than complete sternotomy and partial sternotomy, and 16 minutes longer than right mini-antrolateral thoracotomy ($P < 0.0001$). Quality of mitral valve repair was similar among matched groups ($P = 0.6, 0.2$, and 0.1 , respectively). There were no in-hospital deaths. Neurologic, pulmonary, and renal complications were similar among groups ($P > 0.1$). The robotic group had the lowest occurrences of atrial fibrillation and pleural effusion, contributing to the shortest hospital stay (median 4.2 days), 1.0, 1.6, and 0.9 days shorter than for complete sternotomy, partial sternotomy, and right mini-antrolateral thoracotomy (all $P < 0.001$), respectively.

An early major concern of robotic mitral valve surgery has been the ability to perform complex repairs, such as anterior leaflet or bileaflet repair. Although we began our experience by focusing primarily on posterior leaflet

prolapse, we now feel confident with the robotic approach in patients with anterior or bileaflet prolapse as well. In addition, robotic surgery is offered to patients with mitral valve regurgitation and atrial fibrillation or tricuspid regurgitation.

LIMITATIONS

A significant limitation of contemporary robotic systems is the lack of haptics or tactile feedback. Haptics do for touch what computer graphics do for vision. Although the optics and vision systems have continued to improve dramatically, tactile feedback to the surgeon does not yet exist in robotic surgery. In conventional surgery, almost everything a surgeon does relates to force feedback. The response of tissues to manipulation and the forces applied and given back to the surgeon are essential to identifying pathologic areas, assessing tissue boundaries, and determining the quality of an operation. Currently, surgeons performing robotic surgery assess the force applied to tissue by what they see—how tight tissue appears, how sharp tissue contours are, how subtle color changes are, and so forth. Improving tactile feedback is critical to the continued evolution of robotic technology in minimally invasive surgery.

Another limitation to greater adoption of robotic cardiac surgery is the capital investment required. The cost of \$1.5 million to \$2 million per system (depending on the model, features, service contracts, etc.) plus a per-case cost and additional annual service agreements place it beyond the reach of many institutions. Taking into account these costs, a number of studies have shown higher in-hospital costs for robotic cardiac surgery; this may be shortsighted. In our experience, the per-case cost of robotic surgery is similar to that of conventional surgery when economic outcomes beyond hospital discharge are taken into account.

Longer operative times necessary for robotic mitral valve repair have in part slowed its adoption, although whether or not these longer times affect clinical outcomes remains to be determined. In addition to the setup time for robotic cardiac surgery, a significant portion of time is dedicated to placement of the annuloplasty ring, which is usually anchored with individual mattress sutures that require time-consuming instrument tying. Alternative methods of securing the annuloplasty band, such as a running suture technique or the use of nitinol U-clips (Medtronic, Minneapolis, MN) have shortened operative times and lessened the technical burden of tying a large number of knots endoscopically. In a 2010 report from our institution, a cohort of patients in whom the annuloplasty rings were secured with interrupted sutures ($n = 50$) was compared with a cohort of patients in whom the annuloplasty rings were secured with a running technique ($n = 50$).²¹ Median total procedure (wheels in to wheels out), cardiopulmonary bypass, and aortic occlusion times were significantly decreased by 38, 32, and 19 minutes ($P < 0.01$ in all), respectively, in the running annuloplasty cohort without sacrificing short-term outcomes. In 2007, investigators at Eastern Carolina University reported on a cohort of patients in whom U-clips

were used ($n = 50$) in comparison with a cohort of patients in whom conventional sutures were used ($n = 72$).²⁷ Cardiopulmonary bypass, aortic occlusion, and annuloplasty band placement times were shorter in the U-clip cohort (U-clips versus sutures: 144 ± 50 minutes versus 169 ± 35 minutes, 105 ± 30 minutes versus 132 ± 29 minutes, and 26 ± 5 minutes versus 40 ± 10 minutes, respectively, $P < 0.01$ for all).

Robotic coronary artery bypass surgery continues to be a challenging procedure. The most significant limitation to the success and adoption of robotic bypass surgery is the inability to consistently reproduce a high-quality anastomosis in a timely fashion. Using conventional suture and tying knots adds a significant amount of time to the procedure. Nitinol U-clips (Coalescent Surgical, Inc., Sunnyvale, CA) have been used successfully as an alternative to sutured anastomosis with excellent short-term and mid-term graft patency.^{22,23} Additional alternative methods of creating vascular anastomoses, such as glue or connecting devices, may avert the need to use conventional sutured techniques.^{25,28}

OTHER MINIMALLY INVASIVE APPROACHES

In addition to the robotic approach, many minimally invasive approaches have been described for mitral valve surgery, including the partial sternotomy and right thoracotomy. Common variations of the partial sternotomy include a right-sided partial sternotomy, an upper J incision, a right parasternal incision, and a lower half ministernotomy (T incision).^{1,3,4,17,19,20} Investigators at our institution pioneered the partial upper sternotomy with J incision. Initial results using this approach and an extended transeptal incision were favorable. In our initial experience of 462 cases published in 1999, conversion to a complete sternotomy was necessary in 3%, and there were low rates of wound infection (0.2%), low transfusion requirements, and excellent cosmesis.² In a 2010 report of 590 well-matched patient pairs who underwent conventional minimally invasive surgery versus complete sternotomy, there were cosmetic, blood product use, respiratory, and pain advantages in the minimally invasive cohort with no apparent detriments.⁶ Conventional minimally invasive approaches have since continued to demonstrate improved outcomes and economic benefits over similar surgeries performed through complete sternotomies.³ Given these advantages, mortality and morbidity for robotic and percutaneous mitral valve procedures should be compared with those of conventional minimally invasive approaches rather than with the complete sternotomy.

FUTURE SYSTEMS AND NOVEL VISUALIZATION TECHNIQUES

Technologic advances in cardiac surgery are occurring at a rapid pace. Robotic cardiac surgery has become commonplace for some surgeons. Future incremental modifications and improvements of current systems and

instruments undoubtedly will occur. In addition, novel technology will be developed that will radically change the current paradigm of robotic cardiac surgery and robotic cardiac surgery training.

Current robotic systems are large, take up a lot of space in the operating room, and are cumbersome to move. As technology develops, systems will become smaller, have lower profiles, and be more mobile. Port sizes for the camera and working arms will become even smaller. Further miniaturization may allow for the development of surgical micro-robots, magnetically controlled devices that can be navigated remotely, ingestible cameras, and implantable sensors. Research is currently under way to develop wireless imaging and task-assisting robots that can be placed inside the abdominal cavity during surgery.¹⁵ In addition, investigators at Carnegie Mellon University have described a mobile robotic device that can adhere to the epicardium and navigate to any location in a porcine beating heart model.²⁹

Improving surgical dexterity with haptic feedback is essential to the continued evolution of cardiac surgery, and haptics in robotic surgery is an area of active research. Researchers at Pennsylvania State and Millersville Universities developed a haptic suture simulator that gives a realistic feeling when handling and suturing tissue.⁷ In this simulator, artificial skin deforms relative to the pressure applied to a network of masses and springs through the surgical tool. Specialized software calculates contact forces in the tissue and returns the appropriate forces to the user to simulate the impact of pushing, pulling, cutting, and suturing the skin and underlying tissue. Technology like this could eventually be applied to robotic surgery and allow the surgeon to “feel” the tissue through the robotic arms. The lack of force feedback in current systems makes it possible for the surgeon to inadvertently apply excessive force to the tissue and cause tissue damage. By incorporating haptic feedback into future systems, surgeons will gain a more precise and realistic feel of how tissue is responding to the forces generated by the robotic end-effectors.

Further advancements in visualization will continue to push the field of robotic cardiac surgery forward. In contrast to conventional surgery, the robotic surgeon looks through a vision system rather than directly at the operative field. The three-dimensional display, high definition, and up to 10 $\times$ magnification of the system augment the surgeon's visualization of important structures. In addition, this artificial visualization offers some unique opportunities, such as image stabilization and image overlay. Currently, creation of small-vessel anastomoses on the beating heart is challenging with the robot. Image stabilization systems using a virtual motion compensation scheme are under development with the goal of rendering a motion-stabilized view of the area of interest.¹² Image overlay with the robotic instruments is another unique concept with the robot. Three-dimensional modeling and reconstruction from computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound superimposed with the robotic instruments could provide real-time data acquisition of pathologic characteristics or repair quality. For example, investigators at the University of Western Ontario used real-time three-dimensional

echocardiography as the sole guiding method for atrial septal defect closure in porcine hearts.¹¹ When compared with conventional two-dimensional echocardiography, task completion times were improved by as much as 70%. Investigators at our institution have demonstrated direct endoscopy-guided mitral and tricuspid valve repair in an open-chest, beating-heart bovine model.^{30,31} Using this technique, investigators showed the technical feasibility of beating-heart valve surgery under direct endoscopic imaging. Although the study was performed under open-chest conditions, it is a first step toward closed-chest intracardiac surgery using direct endoscopic visualization. Someday the robotic cardiac surgeon may be able to switch the display and use an alternative imaging source in place of, or in conjunction with, the three-dimensional display to perform beating-heart intracardiac operations.

The future of robotic cardiac surgery is bright. Although years away from full development, it is conceivable that one day a system will exist that will perform fully robotic or automated cardiac surgery. In this scenario, the surgeon will enter all preoperative imaging data on a patient, perform the operation on a virtual simulator, and then transfer the simulation to a robotic telemanipulation system that will perform the operation flawlessly. In addition, a scenario where the operation is planned by software and then performed by a robotic system is imaginable. Although scenarios such as these are years away, existing work has clearly laid the groundwork for automated cardiac surgery.

CONCLUSION

A renaissance in cardiac surgery is under way. Robotic technology is now well established in cardiac surgery and has become standard practice for some surgeons. The success of robotic cardiac surgery is largely the result of advancements in cannulation methods, video optics, instrumentation, and training methods. The development of extrathoracic cardiopulmonary bypass with specialized endovascular cannulas and catheters has allowed for adequate antegrade and retrograde cardioplegic arrest, and ventricular decompression. Enhanced three-dimensional high-definition visualization with the capability of 10× magnification has provided improved clarity and detail of the anastomotic structures. Seven degrees of freedom with the “endo-wrist” instruments, where additional articulation occurs near the tip of the instrument, was critical in improving dexterity in tight spaces. Lastly, the dual-console capability in the newest system allows two surgeons to sit at separate consoles and easily and quickly take control of the instruments at any time during surgery, a situation that helps in training.

Numerous developments must be made in robotic cardiac surgery to increase adoption of robotic technology for coronary revascularization. The creation of robotic coronary vascular anastomoses on a beating heart is technically challenging with current technology, and the inability to consistently reproduce high-quality anastomoses remains a limiting factor in adoption. Improved stabilization devices, automated vascular anastomotic

devices, and the ability to reach all areas of a beating, full heart in a closed chest environment needs to be developed for robotic revascularization surgery to reach its full potential.

Similar to other technologic advances in surgery, robotic cardiac surgery is an evolutionary process. Even the greatest skeptics must concede that substantial progress has been made. In the present era, robotic mitral valve repair has safety and short-term effectiveness profiles similar to those of conventional surgery and has the additional benefits of shorter lengths of stay and faster return to work. Despite enthusiasm, caution cannot be overemphasized because long-term durability of repair has yet to be determined. Any new technology, approach, or technique, including robotic cardiac surgery, must be critically compared with traditional operations, which continue to exhibit long-term success and ever-decreasing rates of morbidity and mortality.

MANAGEMENT OF CARDIAC DEVICES DURING AND AFTER SURGERY

Pacemakers

- Implantable Cardioverter-Defibrillators

HISTORICAL PERSPECTIVE AND OVERVIEW

Paul Zoll developed the first transcutaneous electronic pacemaker in 1952 for the treatment of life-threatening bradycardia.¹ The first internal pacemaker was implanted in 1958 for the treatment of complete heart block² and in the management of Stokes-Adams seizures.³ Early pacemaker models were simple, fixed-rate devices. Thoracic surgeons performed most early implants by placing epicardial leads directly on the exposed heart; these leads were connected to an abdominally implanted pulse generator. Modern pacemakers have sophisticated microprocessors that apply diagnostic and therapeutic algorithms, which have dramatically increased their versatility.

The development of the implantable cardioverter-defibrillator (ICD) was pioneered by Michel Mirowski.⁴⁻⁶ The initial purpose of the ICD was to provide immediate, automatic defibrillation to ambulatory patients who were victims of a lethal ventricular arrhythmia. Mirowski performed the first human ICD implantation in 1980.⁶ First-generation ICDs were composed of large generators (>200 cm³ volume) implanted in an abdominal pocket with epicardial defibrillator patches. Whereas these early ICDs were capable of only high-energy shocks, current ICDs are small (<40 cm³ volume), yet they contain all the advanced pacing functions of modern pacemakers as well as complex tachycardia treatment options (Figs. 85-1 and 85-2). Despite their diminutive size, newer ICDs have become progressively superior in their sensing, diagnosis, and treatment of arrhythmias. Since the late 1990s, ICDs have emerged as the single most effective lifesaving intervention in the prevention of sudden cardiac death.⁷⁻¹¹

With increased sophistication and miniaturization of pulse generators and the development of the much simpler and safer transvenous approach for implantation of cardiac devices, indications for cardiac pacing as well as for ICDs have dramatically expanded.^{12,13} In addition, the U.S. Food and Drug Administration (FDA) approved the totally subcutaneous ICD in September 2012. It is estimated that approximately 400,000 devices are implanted each year in the United States, and there are more than 3 million patients with implanted cardiac devices currently.

FIGURE 85-1 ■ Implantable cardioverter-defibrillators in 1980. (Courtesy Medtronic, Inc., Minneapolis, MN.)

The remainder of this chapter focuses on the description, implantation techniques, indications, and complications of current implantable cardiac pacemakers and defibrillators.

INDICATIONS FOR IMPLANTATION OF CARDIAC DEVICES

The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for device-based therapy of cardiac rhythm abnormalities were updated in 2012.¹⁴

Temporary Pacemakers

Indications

Placement of a temporary pacemaker is indicated whenever hemodynamic compromise is present because of a bradyarrhythmia. Temporary pacemakers should also be placed prophylactically if a high risk for development of hemodynamically intolerated bradycardia is present. Specific guidelines for placement of temporary pacemakers in the setting of acute myocardial infarction exist.¹⁵ Temporary transvenous pacing is indicated in symptomatic sinus bradycardia, sinus pauses of more than 3 seconds, or sinus bradycardia with a heart rate below 40 beats/minute associated with hypotension or hemodynamic compromise, and if unresponsive to a maximum dose (2 mg) of intravenous atropine. Other class I indications for temporary transvenous pacing in acute myocardial infarction include ventricular asystole, alternating left and right bundle branch block, recurrent polymorphic ventricular tachycardia with a heart rate less than 60 beats/minute and prolonged QT, and new bundle branch block or fascicular block and right bundle branch block in the setting of Mobitz II second-degree atrioventricular (AV) block.¹⁵

Venous Access

Table 85-1 summarizes the different sites that can be used for insertion of a temporary pacemaker.¹⁶ The particular patient and the advantages and disadvantages of each site are important factors in the decision of which site to use.

FIGURE 85-2 ■ Implantable cardioverter-defibrillators today. VT/VF, Ventricular tachycardia/ventricular flutter. (Courtesy Medtronic, Inc., Minneapolis, MN.)

TABLE 85-1 Sites for Placement of a Temporary Pacemaker

Site	Advantages	Disadvantages
Femoral vein	Easy access	Leg must remain immobilized High infection risk Fluoroscopy required for proper placement Patient must lie flat
Internal jugular vein	Good site for pacer placement (right better than left)	Risk of pneumothorax, inadvertent carotid artery puncture Patient must lie flat for access; Trendelenburg position preferred to avoid air embolism
Subclavian vein	Good site for pacer placement (left better than right)	Risk of pneumothorax, hemothorax with inadvertent subclavian artery puncture Patient must lie flat for access; Trendelenburg position preferred to avoid air embolism
Antecubital vein (basilic, median basilic, or cephalic)	Access is low risk Good site for pacer placement (left better than right)	Risk of dislodgement; arm must remain immobilized Basilic or median basilic preferred (cephalic has tortuous course to central veins) Fluoroscopy required for pacer placement

From Baim DS, Grossman W, editors: *Grossman's cardiac catheterization, angiography, and intervention*, ed 6, Philadelphia, 2000, Lippincott Williams & Wilkins.

For example, the internal jugular and subclavian veins may be chosen when need for stability and longer pacing requirement is anticipated. If a permanent pacemaker will be required in the future, the temporary pacemaker should be placed through a vein remote from the preferred site for permanent pacemaker implantation. Use of the antecubital veins minimizes bleeding in the coagulopathic patient. However, the risk of cardiac perforation or lead dislodgement is higher if the arm is not kept fully immobilized.

Permanent Pacemakers

Indications

Justifications for permanent pacemaker implantation include alleviation of symptoms and prevention of subsequent morbidity or mortality as a direct result of bradycardia. Bradycardia can result from a variety of disorders of the sinus node, the AV node, the His-Purkinje system, or a combination of these. Sinus node or AV node disease is often not life-threatening but may cause significant symptoms. On the other hand, disease of the His-Purkinje system may be asymptomatic until the development of AV block and its associated severe adverse events.

Symptoms from bradycardia generally result from inadequate cardiac output. Such symptoms may be vague and include fatigue, decreased exercise tolerance, dyspnea

BOX 85-1 Recommendations for Permanent Pacing in Sinus Node Dysfunction

CLASS I

1. Permanent pacemaker implantation is indicated for sinus node dysfunction (SND) with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is indicated for symptomatic chronotropic incompetence. (*Level of Evidence: C*)
3. Permanent pacemaker implantation is indicated for symptomatic sinus bradycardia that results from required drug therapy for medical conditions. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacemaker implantation is reasonable for SND with heart rate less than 40 beats per minute (bpm) when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is reasonable for syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked in electrophysiologic studies. (*Level of Evidence: C*)

CLASS IIB

1. Permanent pacemaker implantation may be considered in minimally symptomatic patients with chronic heart rate less than 40 bpm while awake. (*Level of Evidence: C*)

CLASS III

1. Permanent pacemaker implantation is not indicated for SND in asymptomatic patients. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is not indicated for SND in patients for whom the symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia. (*Level of Evidence: C*)
3. Permanent pacemaker implantation is not indicated for SND with symptomatic bradycardia due to nonessential drug therapy. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: *ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices)* developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

on exertion, lightheadedness, dizziness, congestive heart failure, presyncope, and syncope. Patient-triggered ambulatory cardiac monitoring is often helpful in establishing that such nonspecific symptoms are in fact the result of symptomatic bradycardia. Boxes 85-1 through 85-12 summarize the indications for permanent cardiac pacing published by the ACC/AHA Task Force on Practice Guidelines in 2008 and maintained as part of the 2012 focused update.^{12,14}

Text continued on p. 1491

BOX 85-2 Recommendations for Acquired Atrioventricular Block in Adults**CLASS I**

1. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree atrioventricular (AV) block at any anatomic level associated with bradycardia with symptoms (including heart failure) or ventricular arrhythmias presumed to be due to AV block. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia. (*Level of Evidence: C*)
3. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients in sinus rhythm, with documented periods of asystole greater than or equal to 3.0 seconds or any escape rate less than 40 beats per minute (bpm), or with an escape rhythm that is below the AV node. (*Level of Evidence: C*)
4. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients with atrial fibrillation (AF) and bradycardia with 1 or more pauses of at least 5 seconds or longer. (*Level of Evidence: C*)
5. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level after catheter ablation of the AV junction. (*Level of Evidence: C*)
6. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with postoperative AV block at any anatomic level associated with postoperative AV block that is not expected to resolve after cardiac surgery. (*Level of Evidence: C*)
7. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with neuromuscular diseases with AV block, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms. (*Level of Evidence: B*)
8. Permanent pacemaker implantation is indicated for second-degree AV block with associated symptomatic bradycardia regardless of type or site of block. (*Level of Evidence: B*)
9. Permanent pacemaker implantation is indicated for asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 bpm or faster if cardiomegaly or left ventricular (LV) dysfunction is present or if the site of block is below the AV node. (*Level of Evidence: B*)

10. Permanent pacemaker implantation is indicated for second- or third-degree AV block during exercise in the absence of myocardial ischemia. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacemaker implantation is reasonable for persistent third-degree AV block with an escape rate greater than 40 bpm in asymptomatic adult patients without cardiomegaly. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is reasonable for asymptomatic second-degree AV block at intra- or infra-His levels found at electrophysiologic study. (*Level of Evidence: B*)
3. Permanent pacemaker implantation is reasonable for first- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise. (*Level of Evidence: B*)
4. Permanent pacemaker implantation is reasonable for asymptomatic type II second-degree AV block with a narrow QRS. When type II second-degree AV block occurs with a wide QRS, including isolated right bundle branch block, pacing becomes a class I recommendation. (See Section 2.1.3, "Chronic Bifascicular Block.") (*Level of Evidence: B*)

CLASS IIB

1. Permanent pacemaker implantation may be considered for neuromuscular disease such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease. (*Level of Evidence: B*)
2. Permanent pacemaker implantation may be considered for AV block in the setting of drug use and/or drug toxicity when the block is expected to recur even after the drug is withdrawn. (*Level of Evidence: B*)

CLASS III

1. Permanent pacemaker implantation is not indicated for asymptomatic first-degree AV block. (See Section 2.1.3, "Chronic Bifascicular Block.") (*Level of Evidence: B*)
2. Permanent pacemaker implantation is not indicated for asymptomatic type I second-degree AV block at the supra-His (AV node) level or that which is not known to be intra or infra or infra-Hisian. (*Level of Evidence: C*)
3. Permanent pacemaker implantation is not indicated for AV block that is expected to resolve and is unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea syndrome in the absence of symptoms). (*Level of Evidence: B*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-3 Recommendations for Permanent Pacing in Chronic Bifascicular Block**CLASS I**

1. Permanent pacemaker implantation is indicated for advanced second-degree atrioventricular (AV) block or intermittent third-degree AV block. (*Level of Evidence: B*)
2. Permanent pacemaker implantation is indicated for type II second-degree AV block. (*Level of Evidence: B*)
3. Permanent pacemaker implantation is indicated for alternating bundle branch block. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacemaker implantation is reasonable for syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia (VT). (*Level of Evidence: B*)
2. Permanent pacemaker implantation is reasonable for an incidental finding at electrophysiologic study of a markedly prolonged HV interval (greater than or equal to 100 milliseconds) in asymptomatic patients. (*Level of Evidence: B*)

3. Permanent pacemaker implantation is reasonable for an incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic. (*Level of Evidence: B*)

CLASS IIB

1. Permanent pacemaker implantation may be considered in the setting of neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptoms. (*Level of Evidence: C*)

CLASS III

1. Permanent pacemaker implantation is not indicated for fascicular block without AV block or symptoms. (*Level of Evidence: B*)
2. Permanent pacemaker implantation is not indicated for fascicular block with first-degree AV block without symptoms. (*Level of Evidence: B*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1-e62, 2008.

BOX 85-4 Recommendations for Permanent Pacing after the Acute Phase of Myocardial Infarction**CLASS I**

1. Permanent ventricular pacing is indicated for persistent second-degree atrioventricular (AV) block in the His-Purkinje system with alternating bundle branch block or third-degree AV block within or below the His-Purkinje system after ST-segment elevation myocardial infarction (MI). (*Level of Evidence: B*)
2. Permanent ventricular pacing is indicated for transient advanced second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary. (*Level of Evidence: B*)
3. Permanent ventricular pacing is indicated for persistent and symptomatic second- or third-degree AV block. (*Level of Evidence: C*)

CLASS IIB

1. Permanent ventricular pacing may be considered for persistent second- or third-degree AV block at the AV

node level, even in the absence of symptoms. (*Level of Evidence: B*)

CLASS III

1. Permanent ventricular pacing is not indicated for transient AV block in the absence of intraventricular conduction defects. (*Level of Evidence: B*)
2. Permanent ventricular pacing is not indicated for transient AV block in the presence of isolated left anterior fascicular block. (*Level of Evidence: B*)
3. Permanent ventricular pacing is not indicated for new bundle branch block or fascicular block in the absence of AV block. (*Level of Evidence: B*)
4. Permanent ventricular pacing is not indicated for persistent asymptomatic first-degree AV block in the presence of bundle branch or fascicular block. (*Level of Evidence: B*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1-e62, 2008.

BOX 85-5 Recommendations for Permanent Pacing in Hypersensitive Carotid Sinus Syndrome and Neurocardiogenic Syncope**CLASS I**

1. Permanent pacing is indicated for recurrent syncope caused by spontaneously occurring carotid sinus stimulation and carotid sinus pressure that induces ventricular asystole of more than 3 seconds. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacing is reasonable for syncope without clear, provocative events and with a hypersensitive cardioinhibitory response of 3 seconds or longer. (*Level of Evidence: C*)

CLASS IIB

1. Permanent pacing may be considered for significantly symptomatic neurocardiogenic syncope associated with

bradycardia documented spontaneously or at the time of tilt-table testing. (*Level of Evidence: B*)

CLASS III

1. Permanent pacing is not indicated for a hypersensitive cardioinhibitory response to carotid sinus stimulation without symptoms or with vague symptoms. (*Level of Evidence: C*)
2. Permanent pacing is not indicated for situational vasovagal syncope in which avoidance behavior is effective and preferred. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1-e62, 2008.

BOX 85-6 Recommendations for Pacing after Cardiac Transplantation**CLASS I**

1. Permanent pacing is indicated for persistent inappropriate or symptomatic bradycardia not expected to resolve and for other class I indications for permanent pacing. (*Level of Evidence: C*)

CLASS IIB

1. Permanent pacing may be considered when relative bradycardia is prolonged or recurrent, which limits rehabilitation or discharge after postoperative recovery from cardiac transplantation. (*Level of Evidence: C*)
2. Permanent pacing may be considered for syncope after cardiac transplantation even when bradyarrhythmia has not been documented. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-7 Recommendations for Permanent Pacemakers that Automatically Detect and Pace to Terminate Tachycardias**CLASS IIA**

1. Permanent pacing is reasonable for symptomatic recurrent supraventricular tachycardia (SVT) that is reproducibly terminated by pacing when catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects. (*Level of Evidence: C*)

CLASS III

1. Permanent pacing is not indicated in the presence of an accessory pathway that has the capacity for rapid anterograde conduction. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-8 Recommendations for Pacing to Prevent Tachycardia**CLASS I**

1. Permanent pacing is indicated for sustained pause-dependent ventricular tachycardia (VT), with or without QT prolongation. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacing is reasonable for high-risk patients with congenital long-QT syndrome. (*Level of Evidence: C*)

CLASS IIB

1. Permanent pacing may be considered for prevention of symptomatic, drug-refractory, recurrent atrial fibrillation (AF) in patients with coexisting sinus node dysfunction (SND). (*Level of Evidence: B*)

CLASS III

1. Permanent pacing is not indicated for frequent or complex ventricular ectopic activity without sustained VT in the absence of the long-QT syndrome. (*Level of Evidence: C*)
2. Permanent pacing is not indicated for torsade de pointes VT due to reversible causes. (*Level of Evidence: A*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-9 Recommendation for Pacing to Prevent Atrial Fibrillation**CLASS III**

1. Permanent pacing is not indicated for the prevention of atrial fibrillation (AF) in patients without any other indication for pacemaker implantation. (*Level of Evidence: B*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-10 Recommendations for Cardiac Resynchronization Therapy in Patients with Severe Systolic Heart Failure**CLASS I**

1. Cardiac resynchronization therapy (CRT) is indicated for patients who have left ventricular ejection fraction (LVEF) less than or equal to 35%, sinus rhythm, left bundle branch block (LBBB) with a QRS duration greater than or equal to 150 msec, and New York Heart Association (NYHA) class II, III, or ambulatory IV symptoms on optimal recommended medical therapy. (*Level of Evidence: A for NYHA class III/IV; Level of Evidence: B for NYHA class II*)

CLASS IIA

1. CRT can be useful for patients who have LVEF less than or equal to 35%, sinus rhythm, LBBB with a QRS duration 120 to 149 msec, and NYHA class II, III, or ambulatory IV symptoms on optimal recommended medical therapy. (*Level of Evidence: B*)
2. CRT can be useful for patients who have LVEF less than or equal to 35%, sinus rhythm, a non-LBBB pattern with a QRS duration greater than or equal to 150 msec, and NYHA class III/ambulatory class IV symptoms on optimal recommended medical therapy. (*Level of Evidence: A*)
3. CRT can be useful in patients with atrial fibrillation and LVEF less than or equal to 35% on guideline-directed medical therapy (GDMT) if (a) the patient requires ventricular pacing or otherwise meets CRT criteria and (b) atrioventricular (AV) nodal ablation or pharmacologic rate control will allow near 100% ventricular pacing with CRT. (*Level of Evidence: B*)

4. CRT can be useful for patients on GDMT who have LVEF less than or equal to 35% and are undergoing new or replacement device placement with anticipated requirement for significant (>40%) ventricular pacing. (*Level of Evidence: C*)

CLASS IIB

1. CRT may be considered for patients who have LVEF less than or equal to 30%, ischemic etiology of heart failure, sinus rhythm, LBBB with a QRS duration of greater than or equal to 150 msec, and NYHA class I symptoms on optimal medical therapy. (*Level of Evidence: C*)
2. CRT may be considered for patients who have LVEF less than or equal to 35%, sinus rhythm, a non-LBBB pattern with QRS duration 120 to 149 msec, and NYHA class III/ambulatory class IV on optimal medical therapy. (*Level of Evidence: B*)
3. CRT may be considered for patients who have LVEF less than or equal to 35%, sinus rhythm, a non-LBBB pattern with a QRS duration greater than or equal to 150 msec, and NYHA class II symptoms on optimal medical therapy. (*Level of Evidence: B*)

CLASS III

1. CRT is not recommended for patients with NYHA class I or II symptoms and non-LBBB pattern with QRS duration less than 150 msec. (*Level of Evidence: B*)
2. CRT is not indicated for patients whose comorbidities and/or frailty limit survival with good functional capacity to less than 1 year. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-11 Recommendations for Pacing in Patients with Hypertrophic Cardiomyopathy**CLASS I**

1. Permanent pacing is indicated for sinus node dysfunction (SND) or atrioventricular (AV) block in patients with hypertrophic cardiomyopathy (HCM) as described previously (see Section 2.1.1, "Sinus Node Dysfunction," and Section 2.1.2, "Acquired Atrioventricular Block in Adults"). (*Level of Evidence: C*)

(*Level of Evidence: A*) As for class I indications, when risk factors for sudden cardiac death (SCD) are present, consider a DDD implantable cardioverter-defibrillator (ICD) (see Section 3, "Indications for Implantable Cardioverter-Defibrillator Therapy").

CLASS IIB

1. Permanent pacing may be considered in medically refractory symptomatic patients with HCM and significant resting or provoked LV outflow tract obstruction.

CLASS III

1. Permanent pacemaker implantation is not indicated for patients who are asymptomatic or whose symptoms are medically controlled. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is not indicated for symptomatic patients without evidence of LV outflow tract obstruction. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

BOX 85-12 Recommendations for Permanent Pacing in Children, Adolescents, and Patients with Congenital Heart Disease

CLASS I

1. Permanent pacemaker implantation is indicated for advanced second- or third-degree atrioventricular (AV) block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is indicated for sinus node dysfunction (SND) with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate. (*Level of Evidence: B*)
3. Permanent pacemaker implantation is indicated for postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery. (*Level of Evidence: B*)
4. Permanent pacemaker implantation is indicated for congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction. (*Level of Evidence: B*)
5. Permanent pacemaker implantation is indicated for congenital third-degree AV block in the infant with a ventricular rate less than 55 bpm or with congenital heart disease and a ventricular rate less than 70 bpm. (*Level of Evidence: C*)

CLASS IIA

1. Permanent pacemaker implantation is reasonable for patients with congenital heart disease and sinus bradycardia for the prevention of recurrent episodes of intratrial reentrant tachycardia; SND may be intrinsic or secondary to antiarrhythmic treatment. (*Level of Evidence: C*)
2. Permanent pacemaker implantation is reasonable for congenital third-degree AV block beyond the first year of life with an average heart rate less than 50 bpm, abrupt pauses in ventricular rate that are 2 or 3 times the basic cycle length, or associated with symptoms due to chronotropic incompetence. (*Level of Evidence: B*)
3. Permanent pacemaker implantation is reasonable for sinus bradycardia with complex congenital heart disease with a resting heart rate less than 40 bpm or pauses in ventricular rate longer than 3 seconds. (*Level of Evidence: C*)

4. Permanent pacemaker implantation is reasonable for patients with congenital heart disease and impaired hemodynamics due to sinus bradycardia or loss of AV synchrony. (*Level of Evidence: C*)
5. Permanent pacemaker implantation is reasonable for unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope. (*Level of Evidence: B*)

CLASS IIB

1. Permanent pacemaker implantation may be considered for transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block. (*Level of Evidence: C*)
2. Permanent pacemaker implantation may be considered for congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function. (*Level of Evidence: B*)
3. Permanent pacemaker implantation may be considered for asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate less than 40 bpm or pauses in ventricular rate longer than 3 seconds. (*Level of Evidence: C*)

CLASS III

1. Permanent pacemaker implantation is not indicated for transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient. (*Level of Evidence: B*)
2. Permanent pacemaker implantation is not indicated for asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of prior transient complete AV block. (*Level of Evidence: C*)
3. Permanent pacemaker implantation is not indicated for asymptomatic type I second-degree AV block. (*Level of Evidence: C*)
4. Permanent pacemaker implantation is not indicated for asymptomatic sinus bradycardia with the longest relative risk interval less than 3 seconds and a minimum heart rate more than 40 bpm. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

Cardiac Resynchronization Therapy (or Biventricular Pacing) for the Treatment of Congestive Heart Failure

The 2012 guidelines updated the formal recommendations (see Box 85-10) for cardiac resynchronization therapy (CRT), or biventricular pacing, as an adjunctive treatment for patients with advanced congestive heart failure.¹⁴ Over the past decade, CRT has emerged as a proven therapy for patients with congestive heart failure (New York Heart Association [NYHA] class >II) caused by systolic dysfunction (left ventricular ejection fraction

≤ 35%) with intraventricular conduction delay, generally of the left bundle branch block type. Patients with QRS duration of more than 150 msec have the strongest clinical response to CRT. There is currently no established role for the use of echocardiographic evidence of mechanical dyssynchrony to select patients for CRT. The 2012 guidelines reflected the growing body of evidence that CRT therapy may benefit patients with milder NYHA I and II symptoms in the setting of pronounced intraventricular conduction delay over 150 msec.^{17,18} Intraventricular conduction delay is present in a large proportion of patients with heart failure, and it is frequently

accompanied by mechanical dyssynchrony. Patients who have benefited from biventricular pacing can have systolic dysfunction as a result of either coronary or non-coronary cardiomyopathies. The therapeutic intent is to improve the mechanical efficiency of the heart by simultaneously activating both ventricles with the use of an implantable pacemaker or pacemaker-defibrillator system. Approximately two thirds of patients who are treated with CRT derive clinical benefit that can be demonstrated by improvement in functional status, quality-of-life scores, and objective measures of exercise capacity, as well as decreases in mortality rate and number of heart failure hospitalizations. In addition, the degree of mitral regurgitation frequently present in the patients treated with CRT often improves, as does left ventricular ejection fraction, with biventricular pacing.

Simultaneous pacing of both ventricles is achieved by pacing the right ventricle from a standard transvenous right ventricular apical lead while the left ventricle is paced by a transvenously placed coronary sinus lead. The preferred location for the coronary sinus lead is within the posterolateral coronary sinus vein, where the activation delay is generally most pronounced because of dyssynchronous activation in the setting of the baseline left bundle branch block type of intraventricular conduction delay. [Figure 85-3](#) illustrates typical lead positions for a biventricular pacing system.

Contraindications

Active infection is a contraindication to placement of permanent pacemaker systems. If the need for pacing is urgent, a temporary transvenous pacemaker should be used. In patients with recurrent or protracted infectious illnesses, temporary placement of a standard (screw-in) pacemaker lead is suggested. The proximal end of the lead is externalized and connected to an external pulse generator, and a sterile dressing is placed over the entry

FIGURE 85-3 ■ Fluoroscopic view of a biventricular pacing device. The tip of the coronary sinus (CS) lead is seen within the posterolateral coronary sinus vein.

site. Such temporary systems may be left in place for weeks and may serve as a bridge to implantation of a permanent pacemaker. Alternatively, an epicardial pacing system can be implanted.

Implantable Cardioverter-Defibrillators

Indications

Current ACC/AHA/HRS practice guidelines for ICD therapy are listed in [Boxes 85-13](#) and [85-14](#).¹⁴

A class I indication for ICD therapy is present for patients who survived a cardiac arrest caused by ventricular fibrillation (VF) or hemodynamically significant ventricular tachycardia (VT) not thought to be due to reversible causes. Other class I indications for ICD therapy include spontaneous VT in patients with structural heart disease and syncope of undetermined causes with clinically significant VT or VF induced at electrophysiology study.¹⁴

Several other class I indications for ICD therapy now exist to include the patient population studied in three large clinical trials: MUSTT,⁸ MADIT II,¹⁰ and SCD-HeFT.¹¹ ICD therapy is indicated for patients with left ventricular ejection fraction below 35% (as a result of previous myocardial infarction, who are at least 40 days post myocardial infarction or as a result of nonischemic cardiomyopathy) with functional status consistent with NYHA class II or class III.¹¹ Class I indication for ICD therapy also exists for patients with left ventricular ejection fraction below 30% as a result of previous myocardial infarction (at least 40 days old) who have NYHA class I functional status.¹⁰ In addition, ICD therapy is indicated in patients with left ventricular ejection fraction below 40% as a result of previous myocardial infarction who have nonsustained VT and inducible VT or VF at electrophysiology study.⁸

Other high-risk conditions where ICD therapy is a IIa indication—including arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C), hypertrophic cardiomyopathy, long QT syndrome, and Brugada syndrome—have been addressed in the 2012 societal guidelines (see [Box 85-13](#)).

In September 2012, the FDA approved the totally subcutaneous ICD for the treatment of life-threatening ventricular tachyarrhythmias in patients who do not have symptomatic bradycardia, incessant VT, or spontaneous, frequently recurring VT that is reliably terminated with antitachycardia pacing. These devices hold the promise of lifesaving defibrillation without some of the known problems of transvenous systems, including limited vascular access, transvenous lead durability, hazardous lead extractions, and risks of bloodstream infections. There are no current societal guidelines for which patients should be considered for the S-ICD system.

Contraindications to Implantable Cardioverter-Defibrillator Therapy

If VT/VF is a result of a reversible cause such as acute myocardial infarction or serious electrolyte derangements, ICD implantation is not indicated. An ICD is not

BOX 85-13 Recommendations for Implantable Cardioverter-Defibrillators**CLASS I**

1. Implantable cardioverter-defibrillator (ICD) therapy is indicated in patients who are survivors of cardiac arrest due to ventricular fibrillation (VF) or hemodynamically unstable sustained ventricular tachycardia (VT) after evaluation to define the cause of the event and to exclude any completely reversible causes. (*Level of Evidence: A*)
2. ICD therapy is indicated in patients with structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. (*Level of Evidence: B*)
3. ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study. (*Level of Evidence: B*)
4. ICD therapy is indicated in patients with left ventricular ejection fraction (LVEF) less than 35% due to prior myocardial infarction (MI) who are at least 40 days post MI and are in New York Heart Association (NYHA) functional class II or III. (*Level of Evidence: A*)
5. ICD therapy is indicated in patients with nonischemic dilated cardiomyopathy (DCM) who have an LVEF less than or equal to 35% and who are in NYHA functional class II or III. (*Level of Evidence: B*)
6. ICD therapy is indicated in patients with LV dysfunction due to prior MI who are at least 40 days post MI, have an LVEF less than 30%, and are in NYHA functional class I. (*Level of Evidence: A*)
7. ICD therapy is indicated in patients with nonsustained VT due to prior MI, LVEF less than 40%, and inducible VF or sustained VT at electrophysiologic study. (*Level of Evidence: B*)

CLASS IIA

1. ICD implantation is reasonable for patients with unexplained syncope, significant left ventricular (LV) dysfunction, and nonischemic DCM. (*Level of Evidence: C*)
2. ICD implantation is reasonable for patients with sustained VT and normal or near-normal ventricular function. (*Level of Evidence: C*)
3. ICD implantation is reasonable for patients with HCM who have one or more major risk factors for sudden cardiac death (SCD). (*Level of Evidence: C*)
4. ICD implantation is reasonable for the prevention of SCD in patients with arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) who have one or more risk factors for SCD. (*Level of Evidence: C*)
5. ICD implantation is reasonable to reduce SCD in patients with long-QT syndrome who are experiencing syncope and/or VT while receiving beta blockers. (*Level of Evidence: B*)
6. ICD implantation is reasonable for nonhospitalized patients awaiting transplantation. (*Level of Evidence: C*)
7. ICD implantation is reasonable for patients with Brugada syndrome who have had syncope. (*Level of Evidence: C*)
8. ICD implantation is reasonable for patients with Brugada syndrome who have documented VT that has not resulted in cardiac arrest. (*Level of Evidence: C*)

9. ICD implantation is reasonable for patients with catecholaminergic polymorphic VT who have syncope and/or documented sustained VT while receiving beta blocker. (*Level of Evidence: C*)
10. ICD implantation is reasonable for patients with cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. (*Level of Evidence: C*)

CLASS IIB

1. ICD therapy may be considered in patients with nonischemic heart disease who have an LVEF of less than or equal to 35% and who are in NYHA functional class I. (*Level of Evidence: C*)
2. ICD therapy may be considered for patients with long-QT syndrome and risk factors for SCD. (*Level of Evidence: B*)
3. ICD therapy may be considered in patients with syncope and advanced structural heart disease in whom thorough invasive and noninvasive investigations have failed to define a cause. (*Level of Evidence: C*)
4. ICD therapy may be considered in patients with a familial cardiomyopathy associated with sudden death. (*Level of Evidence: C*)
5. ICD therapy may be considered in patients with LV noncompaction. (*Level of Evidence: C*)

CLASS III

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the class I, IIA, and IIB recommendations above. (*Level of Evidence: C*)
2. ICD therapy is not indicated for patients with incessant VT or VF. (*Level of Evidence: C*)
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. (*Level of Evidence: C*)
4. ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D. (*Level of Evidence: C*)
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. (*Level of Evidence: C*)
6. ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right ventricular (RV) or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). (*Level of Evidence: C*)
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias due to a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). (*Level of Evidence: B*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1-e62, 2008.

BOX 85-14 Recommendations for Implantable Cardioverter-Defibrillators in Pediatric Patients and Patients with Congenital Heart Disease

CLASS I

1. Implantable cardioverter-defibrillator (ICD) implantation is indicated in the survivor of cardiac arrest after evaluation to define the cause of the event and to exclude any reversible causes. (*Level of Evidence: B*)
2. ICD implantation is indicated for patients with symptomatic sustained ventricular tachycardia (VT) in association with congenital heart disease who have undergone hemodynamic and electrophysiologic evaluation. Catheter ablation or surgical repair may offer possible alternatives in carefully selected patients. (*Level of Evidence: C*)

CLASS IIA

1. ICD implantation is reasonable for patients with congenital heart disease with recurrent syncope of undetermined origin in the presence of either ventricular dysfunction or inducible ventricular arrhythmias at electrophysiologic study. (*Level of Evidence: B*)

CLASS IIB

1. ICD implantation may be considered for patients with recurrent syncope associated with complex congenital heart disease and advanced systemic ventricular dysfunction when thorough invasive and noninvasive investigations have failed to define a cause. (*Level of Evidence: C*)

CLASS III

1. All class III recommendations found in Section 3, "Indications for Implantable Cardioverter-Defibrillator Therapy," apply to pediatric patients and patients with congenital heart disease, and ICD implantation is not indicated in these patient populations. (*Level of Evidence: C*)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol* 51:e1–e62, 2008.

recommended for patients who have a terminal illness and whose life expectancy with an acceptable functional status is less than 12 months.¹⁴ Patients who have severe psychiatric disorders whose illness may be exacerbated by ICD shocks or whose illness may preclude proper ICD follow-up may not be appropriate candidates for ICD implantation. In addition, incessant VT/VF that is refractory to medications is also considered a contraindication to ICD implantation until the arrhythmia is controlled by surgical or catheter ablation.

Similar to implantation of permanent pacemakers, ICD implantation is not recommended in patients with active ongoing infection. Patients with infectious issues who have an indication for ICD therapy can undergo

telemetry monitoring in an acute care or rehabilitation facility until their infection is cleared. Alternatively, a wearable external automated defibrillator is now available for patients who are at high risk for sudden cardiac death as a bridge to permanent ICD therapy. This product is manufactured by ZOLL Medical Corporation (Pittsburgh, PA) and was approved by the FDA in 2002.

BASIC CONCEPTS OF PACING AND ANTITACHYCARDIA THERAPY

Permanent Pacemakers

Pulse Generator

Despite the many variations and designs of modern pacemakers, basic components are similar and include power source (battery), circuitry (output, sensing, telemetry, microprocessor, and memory), metal shell (can), ceramic feedthrough (a piece of wire surrounded by glass or sapphire) to provide an electric connection through the can, outlets through which pacing leads are connected to the header of the pacemaker, and sensors.²⁰ Most pacemaker batteries since 1975 are lithium iodide based. Lithium-based batteries have an ideal energy density that has allowed newer pacemakers to be of small volume yet to possess longer battery life. In addition, as opposed to the original mercury-zinc cells, which develop a sudden decrease in voltage shortly before battery depletion, lithium iodide cells have a predictable and gradual decrease in battery voltage as they approach depletion.¹⁹

At the beginning of life, the lithium iodide battery has a voltage output of approximately 2.8 V. The initial decay is slow until the battery approaches depletion, at which time the battery voltage decays more rapidly. When the battery voltage reaches 2.0 to 2.4 V, the elective replacement indicator is triggered, which may precipitate a change in pacing mode (such as dual-chamber to single-chamber pacing), rate response to nonrate response, or a change in magnet rate behavior.²⁰ Once the elective replacement indicator is triggered, the device has approximately 3 to 6 months before it reaches its end of useful life.

The pulse generator is connected with up to three pacing leads and subsequently implanted into a subcutaneous or submuscular pocket (see implantation techniques). The leads are placed under fluoroscopic guidance at standard right atrial, right ventricular, or in the coronary sinus (for left ventricular pacing) locations. The generator is programmed to sense and pace according to a chosen mode that addresses the individual patient's needs.

Pacemaker Leads

Pacing leads are the direct connection between the pulse generator and the myocardium. The distal end of pacing leads consists of one or two exposed metal electrodes that are linked to the pulse generator by insulated wires.

Leads may be unipolar or bipolar; these distinctions apply to both sensing and pacing functions. Unipolar leads have a single electrode incorporated into the lead

(typically the cathode) and the other electrode (typically the anode) incorporated into the generator. Bipolar leads have both electrodes (the anode and the cathode) incorporated into the distal end of the lead. The difference in electrical potential sensed or created (to produce a pacing stimulus) by a bipolar lead occurs over a few millimeters; the difference in a unipolar lead spans the distance between the tip of the lead and the pulse generator across the chest. Bipolar leads possess significant advantages over their unipolar counterparts: no sensing of musculoskeletal potentials that may inappropriately inhibit pacing, less chance of “cross-talk” between the two leads of dual-chamber devices, less chance of interference with an ICD (ICDs should not be used in conjunction with unipolar leads), and less chance of pacing skeletal muscle. In addition, most generators are compatible with unipolar pacing through a bipolar lead if needed as a result of lead damage or high pacing thresholds.

Leads have fixation mechanisms that may be passive (e.g., tines, talons, and fins) or active (e.g., helical screws), both of which are depicted in Figure 85-4. Passive-fixation leads acquire stability by becoming entrapped in myocardial trabeculations. Active-fixation leads have distal screws that are deployed and penetrate the myocardial wall. Active mechanisms carry a lower risk of dislodgement and provide greater versatility in the choice of implantation sites, because their stability does not depend on the presence of trabeculations. However, active-fixation leads generate a more extensive inflammatory response, which may lead to acute rises in pacing threshold after implantation. Steroid-eluting leads are now available to address the problem of acute rise in capture threshold. Such leads have a reservoir of steroid near the electrode that flows through the porous electrode into the myocardium, thereby reducing the inflammatory response and the rise in pacing threshold.²⁰⁻²²

Pacing

Effective cardiac pacing requires the timed introduction of an electrical impulse, which depolarizes nearby myocardium, leading to propagation of an activation wave front. The term *capture* is used to indicate that successful pacing has occurred.¹⁶ The minimum amount of energy required to produce successful myocardial depolarization and pacing is called the stimulation (or pacing) threshold. The pacing energy threshold is a function of the voltage (denoted in volts) delivered by each electrical impulse and the time duration over which the impulse is delivered (pulse width, denoted in milliseconds). For chronic pacing leads, pacing output is conventionally programmed at twofold the value of the pacing threshold voltage or threefold pacing threshold pulse width, considered the safety margin.

Sensing

Sensing is required for the pacemaker to coordinate pacing with any intrinsic electrical cardiac activity. The earliest pacemakers were not able to sense and paced only in VOO mode (see “Basic Pacing Modes,” later). Pacing leads have a recording electrode and an indifferent

FIGURE 85-4 ■ Fixation mechanisms of pacing leads. **A**, Active fixation (screw) mechanism. **B**, Passive fixation (tines) mechanism. (Courtesy Medtronic, Inc., Minneapolis, MN.)

electrode. As a wave of depolarization approaches the recording electrode and then proceeds away from it, it creates what is called an intrinsic deflection, which is the transition from the approaching to the receding deflection. The slope of the intrinsic deflection is called the slow rate. The pacemaker system has an amplifier that increases the signal from the recording electrode and a band pass filter to delete signals with frequencies too high or too low to represent an intrinsic deflection. The electrogram is “sensed” when the amplitude of the filtered signal exceeds the programmed sensing threshold. When sensing occurs, the programmed timing circuits of the pulse generator are reset. In general, a twofold to threefold sensing safety margin is also incorporated in the pacemaker programming. This allows for reliable sensing of activated myocardium but reduces the incidence of far-field oversensing.

Note that pacing intervals and cycle lengths are expressed in milliseconds, and pacing rates are denoted in beats per minute or pulses per minute. Rate and cycle lengths are inversely related and easily converted into one another: rate in beats per minute (or pulses per minute) may be obtained by dividing 60,000 by the cycle length in milliseconds; conversely, cycle length in milliseconds may be determined by dividing 60,000 by the rate in beats per minute (or pulses per minute).

Basic Pacing Modes

A generic pacemaker code allows the uniform functional classification of all pacing systems.

The first three letters are the most widely used and refer to the pacing and sensing functions of the pacemaker.²⁴ The first position denotes the cardiac chambers that may be *paced*, that is, the atrium (A), ventricle (V), both (D), or none (O). The second position refers to the chambers being *sensed*. The third position is used to indicate the *response the pacemaker has to sensing*, or the action performed by the pacemaker in response to sensing of intrinsic electrical activity. The response to sensing events by the pacemaker may be triggered (T), inhibited (I), both (D), or none (O). In a triggered mode, a sensed event leads to delivery of a pacing stimulus. The triggered mode is used to prevent inappropriate inhibition by an incorrectly sensed event, such as skeletal muscle myopotentials. This function can be lifesaving in patients who are pacemaker dependent. The inhibited mode leads to inhibition of stimulus delivery in the designated chamber after sensing of intrinsic electrical activity. When the sensing response is dual (i.e., triggered and inhibited), pacing in the ventricle or atrium does not occur for a programmable time after intrinsic ventricular activity is sensed (i.e., pacing is inhibited). In addition, when the sensing response is dual, sensing of intrinsic atrial activity leads to inhibition of an atrial pacing stimulus, but it results in triggering of a ventricular pacing stimulus after the programmed AV delay.

The fourth position of the generic pacemaker code denotes the *programmability or rate modulation*. The

possible functions at this position include simple programmable (P), multiprogrammable (M), communicating (C), rate modulation (R), or none (O).²⁴ Simple programmable suggests that the programmability of the pacemaker is limited to certain parameters; multiprogrammable pacemakers are able to program a large number of parameters. The communicating function refers to the ability to exchange signals between the pacemaker and a pacemaker programming device. Rate modulation is the most commonly denoted function in the fourth position. It denotes the capability of the pacemaker to adjust the pacing rate according to a sensor device. Pacemaker manufacturers have designed a variety of sensors that attempt to match the individual's physical activity or metabolic demands by responding to different sources, such as motion, temperature, and chest wall impedance (as an estimate of minute ventilation).

The fifth position in the pacemaker code relates to *antitachycardia therapies*: antitachycardia pacing (P), shock (S), dual (D, shock and pacing), or none (O).²³ Since the advent of ICDs, the fifth position is not generally used in referring to pacing systems.

As a result of emerging data that suggest an increased risk of heart failure hospitalization in patients with high burden of right ventricular pacing, algorithms designed to minimize right ventricular pacing have recently become available in pacemakers and defibrillators.²⁴⁻²⁶ Such algorithms provide pacing in AAI mode but will mode switch to DDD whenever necessary if high-grade AV block occurs. If the AV block is transient, the pacing mode will switch back to AAI. Table 85-2 summarizes the most commonly used pacing modes, including advantages and disadvantages of each one as well as their clinical applications.²³ See Figure 85-5 for an example of DDD pacing mode on a 12-lead electrocardiogram.

Implantable Cardioverter-Defibrillators

The guidelines for implantation of ICDs are reviewed earlier in this chapter. Despite the ongoing advancement in the development of today's defibrillators, their primary

TABLE 85-2 Commonly Encountered Pacing Modes

Mode	Advantages	Disadvantages	Clinical Uses
AAI(R)	Requires only a single lead Simple	Slow ventricular rates may develop if atrioventricular (AV) block occurs	Sinus node dysfunction without AV node dysfunction
VVI(R)	Requires only a single lead Simple	During pacing, AV synchrony is not preserved	AV block in a patient with atrial fibrillation
DDD(R)	AV synchrony is maintained for patients with sinus node and AV node disease	Requires two leads More complex	Bradycardia caused by sinus node disease or AV node disease
VDD(R)	AV synchrony is maintained for patients with AV node disease One specially designed lead can be used	AV synchrony is lost if the patient develops sinus bradycardia	Bradycardia caused by AV node disease
DDI(R)	AV synchrony is maintained during atrial pacing	AV synchrony is not maintained during atrial sensing	For patients with bradycardia and intermittent atrial tachycardias Not used as a stand-alone pacing mode but as a mode-switching pacing mode

goal remains to deliver rapid and effective treatment of ventricular tachyarrhythmias.

Pulse Generator

Most ICD generators are currently implanted in the pectoral region. The pulse generator is composed of a lithium/silver vanadium oxide battery and a capacitor. Whereas in 1989, generator volumes exceeded 200 cm³, current generators are less than 40 cm³.²⁷ Progressively smaller ICD generators have become viable as a result of continued progress in battery and capacitor technology. Essential functions that must be reliably performed by the ICD generator include monitoring of cardiac electrical activity through sense amplifiers, analysis of waveforms for the proper diagnosis of arrhythmias, and delivery of appropriate therapy. The lifetime of the battery depends on the battery capacity, and it is inversely related to the number of shocks and to the percentage of time spent in monitoring and pacing.

In addition to the battery and capacitor, the generator houses the operational circuitry of the device, which is composed of low-power circuits (sensing, pacing, amplifiers, microprocessors) and high-power charging and output circuits.²⁷

Leads

Early defibrillators used high-voltage epicardial (or pericardial) electrode patches for defibrillation. These electrode patches were also responsible for sensing, but frequent problems caused by oversensing prompted the use of a separate sensing lead (epicardial or endocardial). With the development of transvenous defibrillators, electrode patches are now only rarely used.

Currently used endocardial leads are made of high-voltage conductors. At least one conductor is used as the defibrillation coil, which is generally found near the tip of the lead and placed along the posterior right ventricular wall. Some leads have two conductors (or two shocking coils). In such dual-coil leads, the distal coil is in the right ventricle and the proximal coil resides anywhere between the subclavian vein, superior vena cava, and right atrium. Separate single-coil leads may instead be implanted in the right ventricle, superior vena cava, coronary sinus, or a combination of these sites; subcutaneous

tissue arrays may also be used. Leads placed in the right ventricle are required to exhibit sensing and pacing capabilities, whereas such functions are not necessary in leads placed in the superior vena cava or coronary sinus.

In general, defibrillation with use of the pulse generator as one of the electrodes can be achieved by lower energies than defibrillation with a combination of leads. The defibrillation threshold (DFT) is the “lowest clinically obtained energy that can achieve defibrillation.”¹⁶ A combination of any three electrodes may be used, instead of two, in an attempt to lower the DFT.

Endocardial ICD leads perform sensing through a distal electrode at the tip of the lead. The same electrode may also be used for pacing. Unipolar ICD leads (normally placed in the superior vena cava or coronary sinus) have a single high-voltage coil used for defibrillation and are not able to pace or sense. Bipolar ICD leads have two conductors, one of which is used for defibrillation and the other for sensing. Such leads sense intrinsic electrical activity between the tip of the lead and anywhere along the extent of the shocking coil (integrated bipolar sensing). In contrast to true bipolar sensing, integrated bipolar sensing more often leads to oversensing because of noise and far-field artifact as well as to undersensing after high-voltage defibrillation.²⁷ Newer defibrillator leads perform true bipolar sensing between the distal tip of the lead and a ring located approximately 1 cm proximal from the tip. Most recently, “quadripolar” leads are now available that perform true bipolar sensing (between the tip of the lead and the ring, as described earlier) and also incorporate two defibrillation coils. In the subcutaneous ICD system, a subcutaneous electrode with a defibrillation coil is tunneled in the skin parallel to the left sternum.

Tachyarrhythmia Detection

Detection of tachyarrhythmias occurs when the device analyzes recent cycle lengths and R-wave morphologies to classify rhythms and to determine appropriate programmed therapy.²⁷ Because some arrhythmias are unsustained, ICDs must effectively be able to detect the arrhythmia, confirm it before delivering therapy, and redetect the arrhythmia if the delivered therapy was unsuccessful. Current devices may be set to have multiple zones of detection (e.g., VT, fast VT, and VF zones) for which specific therapies can be individually programmed (tiered therapy).

Although arrhythmia detection by current ICDs is reliable, inappropriate shocks may still occur even if the device is functioning properly. Such unnecessary shocks most commonly occur in the setting of atrial fibrillation (or other supraventricular tachycardia) or sinus tachycardia if the ventricular rate falls into one of the detection zones.²⁸ Newer and more sophisticated devices have built-in algorithms or additional detection parameters designed to prevent inappropriate shocks by increasing the specificity of VT detection. For safety reasons, these algorithms are available only in the lowest VT rate cutoff zones and include sudden onset and rate stability criteria as well as a criterion based on electrogram morphology.

Tachyarrhythmia Therapy

Current devices can deliver a range of programmable therapies: high-energy defibrillation shocks, low-energy synchronized cardioversion, and antitachycardia pacing (ATP).

High-Energy Defibrillation. As previously described, the DFT is the lowest clinically obtained energy that can accomplish defibrillation. The patient's autonomic and metabolic state may alter the DFT such that an energy output previously able to achieve defibrillation at a particular time may fail at others. Therefore, after the DFT is determined, a safety margin of at least 7 to 10 J is recommended between the maximum output of the device and the DFT. [Figure 85-6](#) depicts an episode of successful defibrillation of VF by a high-energy therapy delivered by an ICD.

Antiarrhythmic drugs may alter the DFT. Amiodarone commonly raises the DFT, whereas sotalol lowers it.^{29,30} Procainamide and quinidine do not appear to affect DFT.³¹ Physicians can consider DFT testing 3 months after initiation of amiodarone to confirm an acceptable safety margin between the DFT and the programmed high-energy defibrillation output.

Low-Energy Synchronized Cardioversions. Low-energy synchronized cardioversions can be delivered faster (shorter charging time) than high-energy defibrillation and may save device battery. Unlike VF, some VT

can be terminated with very low energy therapies, which may cause less discomfort to the patient. Disadvantages of low-energy synchronized shocks include acceleration of VT to VF, which may delay definitive therapy.

Antitachycardia Pacing. Multiple extra stimuli (with or without addition of premature stimuli to a train of extra stimuli) delivered during tachycardia may interact with the tachycardia circuit and thereby terminate it. ATP can be programmed in today's ICDs, and it is widely used as initial therapy for VT. Similar to low-energy synchronized cardioversions, ATP carries the risk of accelerating VT to VF, in which case a high-voltage shock could be delivered to terminate VF. Advantages of ATP as initial therapy for VT include faster delivery time, less discomfort to the patient, and sparing of device battery (if successful). [Figure 85-7](#) shows an example of successful termination of VT by ATP; [Figure 85-8](#) depicts a failed ATP attempt to terminate VT.

PREOPERATIVE EVALUATION BEFORE IMPLANTATION OF CARDIAC DEVICES

Clinical Considerations

A careful history and physical examination should be performed, with focus on the assessment of prior injury or disease within the planned region for device implantation. A history of prior shoulder or chest injury, surgery,

FIGURE 85-8 ■ Failed attempt by antitachycardia pacing to terminate ventricular tachycardia. FVT, Fast ventricular tachycardia.

or radiation therapy may alert the implanting physician of the potential for abnormal venous drainage, which may increase the technical complexity of the implantation. Allergies to medications (including antibiotics, local anesthetic, and intravenous narcotics and benzodiazepines used for conscious sedation) and intravenous contrast material occasionally used for venography should be identified and recorded. It is especially important to recognize and appropriately treat signs and symptoms of active infection before implantation of a permanent cardiac device. Prophylactic antibiotics are administered immediately before and for 72 hours after device implantation. Another essential consideration is the patient's respiratory status. Device implantations generally require that the patient lie flat for the duration of the procedure (up to 2 to 3 hours). Therefore, oxygenation and volume status should be optimized before implantation.

Patients being treated with warfarin or any of the novel oral anticoagulants may remain on anticoagulation therapy during their device implantation. In our institution, it is generally required that the International Normalized Ratio (INR) be less than 3.5 before implantation. We avoid the use of injectable low-molecular-weight heparin or unfractionated heparin bridging around the time of device implantation, because we believe this is associated with greater rates of pocket hematomas.

STANDARD TRANSVENOUS TECHNIQUES FOR IMPLANTATION OF CARDIAC DEVICES

Temporary Transvenous Pacemakers

Percutaneous venous access may be obtained through the internal jugular, subclavian, femoral, or antecubital veins. A lock-down sheath should be introduced in the vein for better lead stability. Fluoroscopy should always be used to guide lead placement when the femoral and antecubital veins are used. The pacing catheter should be advanced to

the right ventricle with care to avoid excessive force that could result in cardiac perforation. The ideal position for the catheter tip is the distal right ventricular septum or inferoapex. The right ventricular free wall and outflow tract should be avoided because of the risk of catheter-induced ectopy and decreased lead stability. After placement of the lead, the sensing and pacing thresholds should be determined. An R wave of 5 mV or more and a pacing threshold of 1 mA or less are adequate. After acceptable placement of the lead has occurred, the sheath should be locked down around the lead. The sheath should then be sutured and the lead secured to the adjacent skin and covered with a dry sterile dressing. A postprocedure chest radiograph should be obtained to confirm lead position and to rule out pneumothorax. At least twice daily, sensing and pacing thresholds should be assessed.

If fluoroscopy is not available, a balloon-tipped catheter should be introduced through the internal jugular or subclavian veins. The distal electrode tip (generally negatively charged) should be connected to one of the precordial leads of a 12-lead electrocardiogram (generally V₁). The limb leads (e.g., lead II) should be recorded and the intracardiac electrogram should be monitored as the balloon-tipped pacing catheter is slowly introduced. When the distal electrode on the tip of the catheter reaches the right atrium, a large atrial electrogram (corresponding to the P wave seen on the limb leads) followed by a smaller ventricular electrogram (corresponding to the QRS on the surface electrocardiogram) should be noted. As the catheter is advanced into the right ventricle, the ventricular electrogram grows larger and the atrial signal becomes smaller. Once the tip of the pacing catheter comes in contact with the myocardium, an injury current (reminiscent of ST elevation) will be recorded immediately after the ventricular electrogram, and the catheter should not be advanced farther. After the pacing catheter is positioned and secured, a 12-lead electrocardiogram should always be obtained to corroborate, on the basis of the morphology of the paced QRS complexes, proper positioning of the catheter.

When asystole (or severe bradycardia) is present, the pacing electrode tips (distal and proximal) should be connected to an active pacing box (or generator) programmed to pace in VVI mode. Paced QRS complexes should emerge once contact of the catheter tip to myocardium occurs.

When temporary atrial (instead of ventricular) or AV sequential pacing is required, a temporary pacing catheter/lead can be placed in the right atrium (active-fixation lead) or in the coronary sinus. The atrial pacing threshold is generally higher in the coronary sinus than in the right atrium.

Duration of temporary pacing should be limited to less than 72 hours to minimize the risk of infection, cardiac perforation, and lead dislodgement. Active-fixation leads connected to an externalized pacemaker generator may be left in place for longer periods.

Permanent Pacemakers

Most permanent transvenous pacemakers are placed in the right or left pectoral region through the cephalic, axillary, or subclavian veins. A peripheral intravenous catheter should be placed on the upper extremity ipsilateral to the planned implant in case venography is necessary to define the anatomy or availability of access. Unless the patient is left-handed or the left side is inaccessible, the left pectoral region is preferable because of greater simplicity of lead placement and manipulation. Prophylactic antibiotics should be administered as described earlier, and the pectoral region should be prepared and draped in sterile fashion.

Cephalic Vein (Cutdown) Approach

Local anesthetic is delivered to the pectoral region. An oblique incision is made over the deltopectoral groove and extended inward by use of blunt dissection. Alternatively, a horizontal incision 2 cm below the clavicle (with its lateral border extending over the deltopectoral groove)

may be chosen. The cephalic vein runs in the deltopectoral groove, which can be identified by the presence of a fatty streak between the pectoralis and deltoid muscles. Once the cephalic vein is identified, it should be dissected free from the surrounding fat and connective tissue. [Figure 85-9](#) illustrates the anatomic location of the subclavian, axillary, and cephalic veins.

A 0 silk suture is placed around the vein (but not tied) proximally and another one distally, and a 5 French (Fr) dilator is placed in the vein. Under fluoroscopic guidance, a guidewire is introduced into the 5 Fr dilator and advanced to the inferior vena cava through the subclavian vein, the superior vena cava, the right atrium, and into the inferior vena cava; the 5 Fr dilator is then removed. Venography may be necessary through the 5 Fr introducer or a peripheral line to establish patency of the vessels or to define the venous anatomy if difficulty in advancing the wire is encountered.

Axillary Vein Approach

The axillary vein can be cannulated through the same cutdown location in the deltopectoral region. The axillary vein is accessed through a single wall puncture technique by landmarks or direct visualization through venography.

Subclavian Vein Approach

The subclavian vein may also be accessed by a single wall puncture technique. The subclavian vein approach is generally the least desirable because of the risk of pneumothorax and the potential risk of crush injury to the pacing leads as they pass between the clavicle and first rib.

Technique

Regardless of the vein used for access, a guidewire is advanced to the inferior vena cava under fluoroscopic

FIGURE 85-9 ■ Anatomic illustration of the subclavian, axillary, and cephalic veins. (Modified from Agur AMR, Lee MJ: Upper limb. In *Grant's atlas of anatomy*, ed 10, Philadelphia, 1999, Lippincott Williams & Wilkins.)

guidance. Once venous access has been secured and the guidewire positioned, sheaths (or introducers) are used for sequential placement of atrial and ventricular leads. While a lead is being placed through the sheath, the patient should be instructed to transiently refrain from talking or breathing to avoid complication by air embolus through the introducer sheath. The fluoroscopic view for optimal placement of the right ventricle lead is generally obtained from the right anterior oblique position. This view allows proper visualization of the full length of the right ventricle (foreshortened in the anteroposterior view). Adequate lead position along the right ventricular inferoseptum and apex should also be confirmed in the left anterior oblique view. Ventricular ectopy may occur during lead placement, but it is generally transient. If there is persistent VT, the lead should be repositioned. If VT continues despite lead repositioning, the rhythm should be terminated by ATP or defibrillation.

Ventricular sensing and pacing thresholds should be checked, and the QRS morphology in lead V₁ should be assessed to confirm that pacing originates from the right ventricle (left bundle branch block morphology should be present in lead V₁). When a right bundle branch block morphology is present in lead V₁, pacing from the left ventricular endocardium (through an atrial or ventricular septal defect), from the coronary sinus, or from the left ventricular epicardium (as a result of cardiac perforation) should be suspected. On occasion, a right bundle branch block morphology will be seen with pacing from the right ventricular septum.

The atrial lead is generally placed in the right atrial appendage if it is present. Use of a curled wire stylet will enable positioning in the right atrial appendage. However, any location in the right atrium is acceptable if it is stable, provided no excessive sensing of the ventricular electrogram is present.

Once acceptable positions for both leads have been obtained, lead stability should be confirmed during coughing and deep breathing exercises. Lead locations should be confirmed from the right anterior oblique and left anterior oblique views. High-output pacing should be performed from both leads to rule out diaphragmatic capture during pacing. Stylets and guidewire should be removed, and proper amount of slack in each lead should be ensured fluoroscopically. After optimal lead positions are confirmed, the leads should be secured to the pectoralis muscle with nonabsorbable suture tied around anchoring sleeves. Final sensing and pacing thresholds should be checked after the leads have been sutured to the pectoralis fascia.

After the leads are secured, local anesthesia is administered to the subcutaneous tissues medial to the deltopectoral groove to create a subcutaneous (or submuscular) pocket for the device generator. The pocket is created by blunt dissection and copiously irrigated. The leads are then connected to the pulse generator according to the indicated positions. The leads are coiled under the generator, and the entire system is implanted into the pocket. Proper sensing and pacing by the device should be confirmed.

The subcutaneous tissues are closed with absorbable suture, and the skin is closed with a subcuticular layer of

absorbable suture or staples. A dry sterile dressing should be placed over the wound.

Implantation of single-chamber devices is done by the same technique except for placement of the second lead. [Figure 85-10](#) depicts a chest radiograph with the expected lead position for a single-chamber transvenous pacemaker.

As discussed previously, the biventricular pacing of both left and right ventricles is appropriate in a particular heart failure patient population. The left ventricle is paced through a passive pacing lead that is advanced through the coronary sinus into a posterolateral vein. If an implanting physician is unable to achieve an optimal location for coronary sinus pacing, an epicardial lead can be placed surgically.

Implantable Cardioverter-Defibrillators

Surgical techniques to implant epicardial patches used in early ICDs are not discussed in this chapter. Instead, this chapter concentrates on the transvenous implantation of current cardioverter-defibrillators.

The left pectoral region is preferred for most ICD implants, whether the patient is right- or left-handed. The coil configuration obtained with a left-sided implant allows a more effective field orientation for defibrillation, when one of the shocking electrodes lies within the pulse generator. The technique used to place modern transvenous ICDs is the same as the technique described to implant transvenous permanent pacemakers (see earlier), although the first transvenous ICDs required abdominal pulse generators because of their large size (transvenous leads were tunneled subcutaneously to the abdomen, where the generator was implanted). Also, subcutaneous patches or arrays were often necessary in early ICDs to achieve acceptable DFT. In [Figure 85-11](#), a postprocedure chest radiograph confirms appropriate lead positions in a dual-chamber transvenous ICD.

FIGURE 85-1 ■ Posteroanterior chest radiograph showing appropriate lead position for a single-chamber transvenous pacemaker.

FIGURE 85-11 ■ Posteroanterior chest radiograph showing appropriate lead positions for a dual-chamber transvenous implantable cardioverter-defibrillator.

Recently, the use of a fully subcutaneous ICD has become an option in a selected patient population. In this system, the pulse generator is placed within a pocket created between the fourth and fifth intercostal spaces at the midaxillary line. An electrode is positioned through two subcutaneous tunnels, extending from the pocket to a small xiphoid incision and from the xiphoid to a superior sternal incision.

Defibrillation Threshold Testing

The procedure for any ICD implant can include defibrillation testing to determine the DFT. The prevailing rationale for the routine evaluation of DFTs has been to ensure appropriate sensing of ventricular fibrillation, system integrity, and effective defibrillation. Defibrillation testing is generally performed before wound closure, after the leads are connected to the pulse generator and after the system is implanted into the pocket.

The programmer is used to communicate with the device through a sterile wand placed over the pocket. Recently, wireless devices are available that can communicate with the programmer without physical contact once initial connection with the generator has been established. Before VF induction and ICD testing, some operators deliver a low-energy synchronized shock to allow confirmation of intact connections by checking the high-voltage lead impedance. External defibrillation hands-off pads are also placed and connected to an external biphasic defibrillator in the event of device failure to terminate VF. Testing is generally performed at the least sensitive device setting for detection of VF to ensure an adequate safety margin. After successful testing, the device is programmed at the most sensitive setting for VF detection. VF is most commonly induced by timed

T-wave shocks or by rapid-burst ventricular pacing at 50 Hz.

At our institution, initial testing is performed with a selected energy (10 J lower than the maximum device output) that allows an adequate safety margin between the tested energy and the maximum device output (margin-verification protocol). A second shock with a lower energy is often performed. Before testing, we generally set the second device therapy as a maximum output shock, which is delivered if the first tested energy fails and after VF is redetected. If a high-output shock through the device fails to terminate VF, a 360-J biphasic shock is externally delivered.

Normally, a 5-minute “rest” period is provided between each induction of VF. Other important parameters evaluated during ICD testing include the high-voltage lead impedance and the charge time for delivery of high-voltage therapies. If an adequate DFT is not obtained during testing, addition of extra defibrillation coils (including subcutaneous arrays or patches), reversal of shock polarity, or repositioning of the right ventricle lead may be necessary. A 7- to 10-J safety margin should be incorporated in the final therapy programming of the device. After an acceptable DFT is obtained, the wound is closed as described previously.

Contemporary ICD systems using active cans, pectoralis pulse generators, biphasic waveforms, and intravascular high-voltage leads have considerably lowered the incidence of elevated DFTs. The reliability of current ICD systems has led to recent literature reevaluating the necessity for routine DFT testing at ICD implantation.³²⁻³⁴ As such, observational studies have noted an elimination of DFT testing in one third of initial implants and two thirds of replacements. A study estimates that 5-year survival is expected to be higher in patients who undergo DFT testing at implantation only if the annual risk of a lethal arrhythmia (or the risk of a narrow safety margin) is at least 5%.³² At our institution, we no longer perform routine DFT testing at the time of device implantation or generator change.

POSTIMPLANTATION CARE OF TRANSVENOUS CARDIAC DEVICES

Patients undergoing implantation of electrophysiologic cardiac devices should be observed overnight in the hospital. Continuous telemetry monitoring should be performed during this time to allow early diagnosis and treatment of lead malfunction or dislodgement (the most common complication in the early postoperative period). Bed rest is recommended overnight, and the arm ipsilateral to the implant is placed in a sling for 24 hours. The patient is allowed to move that arm after 24 hours, but lifting of objects weighing more than 5 to 10 pounds and raising the arm above shoulder level should be avoided for 6 weeks after the procedure. A posteroanterior and lateral chest radiograph should be obtained on the morning after implantation to assess adequate lead and generator positions. If the subclavian vein was used for venous access, a portable chest radiograph is required immediately after implantation to rule out

pneumothorax. Anticoagulation with intravenous heparin or low-molecular-weight heparin should be avoided for at least the first 8 hours after implantation. We recommend the continuation of oral anticoagulation of patients through their device implantation if they are already on blood-thinning medication. The use of prophylactic antibiotics should be prescribed as described previously.

The device should be interrogated on the day after implantation to ensure proper device function and to fine-tune the device programming if necessary. The wound should be kept dry for at least 3 days after implantation. A follow-up appointment should be scheduled within 7 to 10 days of discharge for wound check and device reinterrogation. Marked changes in lead impedance and in pacing and sensing thresholds would be identified at that time and could indicate lead dislodgement or malfunction.

COMPLICATIONS OF IMPLANTABLE CARDIAC DEVICES

Serious complications of device implantation occur in less than 2% of patients undergoing the procedure. Procedural complications may be classified as early, which may include intraoperative, perioperative (within 24 hours), or postoperative complications (after 24 hours but within 30 days of the procedure), or late, occurring after 30 days from the procedure.

Examples of early complications are outlined in [Box 85-15](#) and include bleeding, vascular injury, infection, pneumothorax, hemothorax, air embolus, cardiac

perforation or tamponade, rhythm abnormalities, deep venous thrombosis, pulmonary embolism, lead dislodgement, lead fracture or damage, and pocket hematoma. Late complications are also listed in [Box 85-15](#) and may include lead fracture or insulation break, lead dislodgement, pocket skin erosion, infection, migration of generator possibly leading to lead twisting and fracture, and deep venous thrombosis or scarring. [Figure 85-12](#) shows an example of skin erosion with subsequent infection of a device pocket.

EXTRACTION OF CHRONIC LEADS USED IN TRANSVENOUS CARDIAC DEVICES

Overview

Since the introduction of transvenous pacing electrodes in 1958 by Furman and Schwedel,³ techniques to safely remove such leads have been developed and perfected. Earlier techniques focused on the simple use of traction, which can be done safely and without the assistance of specially designed tools only in recently implanted leads (generally, implants less than 1 year old) that have not developed significant fibrosis. For more chronic leads, complications preclude the use of simple traction, and surgical approaches that require sternotomy or thoracotomy were initially the only viable options. Since the mid-1980s,³⁵⁻³⁸ safer transvenous methods for chronic lead extraction have been developed.

Official definitions and guidelines for the practice of transvenously placed lead extractions were published in 2000, and subsequently updated in 2009.^{39,40} The term *lead extraction* is reserved only for the removal of a lead that requires specialized equipment (laser sheath, traction devices, electrosurgical sheaths, rotational threaded tip sheaths, or telescoping sheaths) or from a route other than the implant vein and of any lead implanted for more than 1 year. A complete summary of indications for lead extraction is provided in [Box 85-16](#). Class I indications include serious illness caused by an infected lead, clinical need for a new transvenous cardiac device when all usable veins are obstructed, and malfunctioning, fractured, or

BOX 85-15 Early and Late Complications of Implantable Cardiac Devices

EARLY

- Bleeding
- Infection
- Pneumothorax, hemothorax
- Cardiac perforation
- Superior vena cava perforation
- Lead migration or dislodgement (2%)
- Air embolus
- Venous thrombosis
- Atrial tachyarrhythmias
- Ventricular tachycardia
- Atrioventricular (AV) block by contact injury to the conduction system
- Pocket hematoma

LATE

- Infection of device pocket or leads (2.7%)
- Pocket erosion, wound breakdown
- Lead fracture, insulation damage (0.2%)
- Venous thrombosis
- Chronic pain
- Tricuspid regurgitation
- Left ventricular dysfunction
- Migration of pulse generator
- Twisting or fracture of leads due to manipulation of generator (twiddler syndrome)

FIGURE 85-12 ■ Example of skin erosion and subsequent infection of device pocket. (Courtesy Medtronic, Inc., Minneapolis, MN.)

BOX 85-16 Indications for Lead Removal/Extraction by Transvenous Techniques**INFECTION****Class I**

1. Definite system infection, as evidenced by valvular endocarditis, lead endocarditis, or sepsis
2. Pocket infection as evidenced by pocket abscess, device erosion, skin adherence, or chronic draining sinus
3. Valvular endocarditis without definite involvement of the lead(s) and/or device
4. Occult gram-positive bacteremia (not contaminant)

Class IIa

1. Persistent occult gram-negative bacteremia

Class III

1. Not indicated for a superficial or incisional infection without involvement of the device and/or leads
2. Not indicated to treat chronic bacteremia due to a source other than the cardiovascular implantable electronic device (CIED), when long-term suppressive antibiotics are required

CHRONIC PAIN**Class IIa**

1. Severe chronic pain, at the device or lead insertion site, that causes significant discomfort for the patient

THROMBOSIS AND VENOUS STENOSIS**Class I**

1. Significant thromboembolic events associated with thrombus on a lead or a lead fragment
2. Bilateral subclavian vein or superior vena cava (SVC) occlusion precluding implantation of a needed transvenous lead
3. SVC stenosis or occlusion with limiting symptoms
4. Ipsilateral venous occlusion preventing access to the venous circulation for required placement of an additional lead when there is a contraindication for using the contralateral side (e.g., contralateral AV fistula, shunt or vascular access port, mastectomy)

Class IIa

1. Ipsilateral venous occlusion preventing access to the venous circulation for required placement of an additional lead, when there is no contraindication for using the contralateral side

FUNCTIONAL AND NONFUNCTIONAL LEADS**Class I**

1. Life-threatening arrhythmias secondary to retained leads
2. Lead design failure that poses an immediate threat to the patient if left in place
3. Leads that interfere with the treatment of a malignancy (radiation/reconstructive surgery)

Class IIa

1. Nonfunctional leads that due to design failure pose a threat to the patient that is not immediate or imminent if left in place
2. Nonfunctional lead removal to avoid more than four leads on one side or more than five leads through the SVC
3. Nonfunctional lead removal is reasonable in patients that require specific needed imaging techniques and cannot be imaged due to the presence of the device

Class IIb

1. Functioning leads that due to design failure pose a potential future threat to the patient if left in place
2. Functional leads not being used
3. To permit the implantation of a magnetic resonance imaging (MRI)-compatible system
4. At the time of an indicated device implantation in patients with nonfunctional leads

Class III

1. Not indicated if patient has a life expectancy of less than 1 year
2. Not indicated in patients with known anomalous placement of leads through structures other than normal venous and cardiac structures unless clinical situation compelling

From Love CJ, Wilkoff BL, Byrd CL, et al: Recommendations for extraction of chronically implanted transvenous pacing and defibrillator leads: indications, facilities, training. North American Society of Pacing and Electrophysiology Lead Extraction Conference Faculty. *Pacing Clin Electrophysiol* 23(4 Pt 1):544-551, 2000.

suboptimally positioned leads that pose danger to the patient. Relative contraindications to transvenous lead extraction include lead calcification (detected on radiography) involving the right atrium or the superior vena cava, unavailability of suitable equipment, patient's clinical condition that precludes emergent thoracotomy or less than 1 year survival, or lead placement through unusual routes (e.g., subclavian artery, pericardial space). Because of the potentially serious complications of transvenous lead extractions, physicians properly trained in these techniques and adequately equipped institutions are absolute requirements for the performance of lead extractions.

Data from the U.S. Extraction Database for intravascular extraction of infected or problematic pacemaker

leads from January 1994 to April 1996 were published in 1999.⁴¹ In this series, the success rate was 93% for complete removal of the leads and 5% for partial removal of the leads; 2% failed. Major complications occurred in 1.4% of patients (<1% in centers that performed >300 extractions) and minor complications in 1.7% of patients. Major complications occurred more frequently in women. Predictors of incomplete lead removal or failure included longer implant duration, less experienced operators, ventricular lead location, noninfected leads, and younger age of the patient. Reports using the more modern laser lead extraction technique involving 2561 pacing and defibrillator leads in 1684 patients at 89 sites describe a procedural success rate of 90% with a major complication rate of 1.9% with an in-hospital death rate of 0.8%.⁴²

Tools Used in Chronic Lead Transvenous Extractions

Angiographic Catheters, Snares, Forceps, and Locking Stylets

Angiographic catheters that are commonly used to assist in lead extractions include the angled pigtail catheter, the Judkins right coronary catheter, the multipurpose coronary catheter, and the Amplatz catheter. These catheters are used in combination with common guidewires or tip-deflecting guidewires that loop around or hook onto the pacemaker lead to retrieve it. This approach may also be used to retrieve loose lead ends or free-floating lead remnants. Other tools used include the basket retriever catheter, the Dotter intravascular retriever (helical loop basket) that gets irreversibly entrapped in the lead, and the Dormia basket.

Different types of snares are also available and are used in conjunction with catheters and guidewires to recover and to extract chronic pacemaker leads. Examples of snares include the Curry snare (used to form a wire-loop system), the Amplatz gooseneck snare (loop at a right angle to the guidewire), and the Needle's Eye snare created by Cook Vascular, Inc. (consisting of a hoop-shaped loop and a locking slide threader), which provides a reversible system able to release the seized object. Cook Vascular, Inc., has also developed a "locking stylet" that is efficient in seizing and holding the lead while preventing the lead from stretching or uncoiling as it is being retrieved.⁴³

Forceps (grasping forceps, alligator forceps, and myocardial bicep forceps) have also been used for lead extractions. This stylet intensifies the tensile power of the lead and directs the extraction force to the tip of the lead. The locking system is engaged and released by counterclockwise and clockwise rotation, respectively.

Byrd Dilator Sheaths

These sheaths were marketed by Cook Vascular, Inc., and may be used to assist with extractions performed through the implant vein. They consist of telescoping stainless steel sheaths with metal dilators that are advanced over the lead to sever through the thick fibrous adhesions found at the venous entry site and distal ends of chronic leads. Once entrance to the vein is attained, the metal dilators are exchanged for telescoping flexible plastic sheaths that are able to negotiate the turns.

Excimer Laser Sheaths

Excimer laser sheaths were developed by Charles Byrd and are used in association with the Spectranetics CVX-300 excimer laser system.⁴³ The laser sheath contains a ring of optical fibers at its distal tip able to emit pulses of ultraviolet light that destroy the surrounding fibrous tissues around the lead. Mild countertraction and counterpressure activate the laser. An advantage of the laser system is that tissue vaporization is achieved, as opposed to blunt tissue dissection and shredding. One disadvantage is that the system is not effective against

calcifications, which are often encountered around older leads.

Electrosurgical Dissection Systems

The most recent advancement in lead extraction equipment includes the electrosurgical dissection system developed by Cook Vascular, Inc. Such systems use radio-frequency energy (instead of laser or blunt dissection) to destroy the fibrous endovascular adhesions that anchor device leads to venous walls. The most recent radiofrequency-based system has a dual electrode scheme that performs a bipolar dissection while also functioning as a mechanical dissection sheath. The tip electrode spacing is such that it effectively localizes the disruptive energies to the specific regions interfering with extraction of the lead, as opposed to circumferentially obliterating the endovascular border.

Techniques of Chronic Lead Transvenous Extractions

Transvenous lead extractions should preferably be performed in a setting appropriate for emergent thoracotomy; a cardiothoracic surgeon should be promptly available. Before any transvenous extraction of chronic pacemaker leads, the patient should be prepared in advance for potential thoracotomy. Intra-arterial blood pressure monitoring is recommended. Transthoracic and transesophageal echocardiography and a pericardiocentesis tray should be readily accessible to allow expeditious diagnosis and treatment of possible complications. A temporary pacing wire should be placed through the femoral vein if the patient is pacemaker dependent.

Extraction through the Implant Vein
